5 1 Introduction

32

33

35

37

38

40

The characteristic feature of collisions at the LHC is a center-of-mass energy, 7 TeV in 2010 and 2011, of 8 TeV in 2012, and near 14 TeV with the start of the second 59 phase of operation in 2015, that is large compared to 60 even the heaviest of the known particles. Thus these 61 10 particles (and also previously unknown ones) will often 62 11 be produced at the LHC with substantial boosts. As a 63 12 result, when decaying hadronically, these particles will 64 not be observed as multiple jets in the detector, but 65 rather as a single hadronic jet with distinctive internal 66 substructure. This realization has led to a new era of 67 sophistication in our understanding of both standard 68 17 QCD jets and jets containing the decay of a heavy par-69 ticle, with an array of new jet observables and detection 70 19 techniques introduced and studies. To allow the efficient 71 20 sharing of results from these jet substructure studies a 72 21 series of BOOST Workshops have been held on a yearly 22 basis: SLAC (2009, [?]), Oxford University (2010, [?]), Princeton University University (2011, [?]), IFIC Va-24 lencia (2012 [?]), University of Arizona (2013 [?]), and, most recently, University College London (2014 [?]). Af-73 26 ter each of these meetings Working Groups have func-27 tioned during the following year to generate reports 28 highlighting the most interesting new results, includ-29 ing studies of ever maturing details. Previous BOOST reports can be found at [?,?,?]. 31

This report from BOOST 2013 thus views the study $^{76}\,$ and implementation of jet substructure techniques as a $^{77}\,$ fairly mature field, and focuses on the question of the 78 correlations between the plethora of observables that 79 have been developed and employed, and their depen- 80 dence on the underlying jet parameters, especially the 81 jet radius R and jet p_T . Samples of quark-, gluon-, W- 82 and Top-initiated jets are reconstructed at the particle-83 level using FastJet[REF], and the performance, in 84 terms of separating signal from background, of vari-85 ous groomed jet masses and jet substructure observ- 86 ables investigated through Receiver Operating Char-87 acteristic (ROC) curves, which show the efficiency to 88 "tag" the signal as a function of the efficiency (or re-89 jection, being 1/efficiency) to "tag" the background. 90 We investigate the separation of a quark signal from 91 a gluon background (q/g tagging), a W signal from a 92 gluon background (W-tagging) and a Top signal from a mixed quark/gluon QCD background (Top-tagging). In the case of Top-tagging, we also investigate the performance of dedicated Top-tagging algorithms, the Hep-TopTagger[REF] and John Hopkins Tagger[REF]. Using multivariate techniques, we study the degree to which the discriminatory information provided by the observables and taggers overlaps, by examining in particular the extent to which the signal-background separation performance increases when two or more variables/taggers are combined, via a Boosted Decision Tree (BDT), into a single discriminant.

The report is organized as follows. In Section 2 we describe the generation of the Monte Carlo event samples that we use in the studies that follow. In Section 3 we detail the jet algorithms, observables and taggers investigated in each section of the report, and in Section 4 the multivariate techniques used to combine the one or more of the observables into single discriminants. In Section 5 we describe the q/g-tagging studies, in Section 6 we describe the W-tagging studies, and in Section 7 we describe the Top-tagging studies. Finally we offer some summary of the studies and general conclusions in Section 8.

2 Monte Carlo Samples

2.1 Quark/gluon and W tagging

Samples were generated at $\sqrt{s}=8$ TeV for QCD dijets, and for W^+W^- pairs produced in the decay of a (pseudo) scalar resonance and decaying hadronically. The QCD events were split into subsamples of gg and $q\bar{q}$ events, allowing for tests of discrimination of hadronic W bosons, quarks, and gluons.

Individual gg and $q\bar{q}$ samples were produced at leading order (LO) using Madgraph5, while W^+W^- samples were generated using the JHU Generator to allow for separation of longitudinal and transverse polarizations. Both were generated using CTEQ6L1 PDFs[REF]. The samples were produced in exclusive p_T bins of width 100 GeV, with the slicing parameter chosen to be the p_T of any final state parton or W at LO. At the parton-level the p_T bins investigated were 300-400 GeV, 500-600 GeV and 1.0-1.1 TeV. Since no matching was performed, a cut on any parton was equivalent. The samples were then all showered through Pythia8 (version 8.176)[REF]using the default tune 4C[REF].

ED: Need to report the size of the samples used

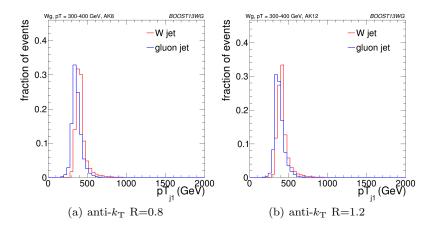

Fig. 1 Comparisons of the leading jet p_T spectrum of the gg background to the WW signal in the p_T 300-400 GeV parton p_T slice using the different anti- k_T jet distance parameters explored in this p_T bin. These distributions are formed prior to the 300-400 GeV leading jet p_T requirement.

95 2.2 Top tagging

Samples were generated at $\sqrt{s}=14$ TeV. Standard₁₂₆ Model dijet and top pair samples were produced with₁₂₇ SHERPA 2.0.0[**REF**], with matrix elements of up to two₁₂₈ extra partons matched to the shower. The top sam-₁₂₉ ples included only hadronic decays and were generated₁₃₀ in exclusive p_T bins of width 100 GeV, taking as slicing parameter the maximum of the top/anti-top p_T . The QCD samples were generated with a cut on the leading parton-level jet p_T , where parton-level jets are clustered with the anti- k_t algorithm and jet radii of R=0.4, 0.8, 1.2. The matching scale is selected to be $Q_{\rm cut}=40,60,80$ GeV for the $p_{T\,\rm min}=600,1000,$ and $q_{\rm cut}=40,60,80$ GeV for the $q_{T\,\rm min}=600,1000,$ and $q_{\rm cut}=40,60,80$ GeV for the $q_{T\,\rm min}=600,1000,$ and $q_{\rm cut}=600,1000,$ such that $q_{\rm cut}=600,1000,$ such that $q_{\rm cut}=600,1000,$ are size of the samples used

3 Jet Algorithms and Substructure Observables

In this section, we define the jet algorithms and observables used in our analysis. Over the course of our study, we considered a larger set of observables, but for the final analysis, we eliminated redundant observables for presentation purposes. In Sections 3.1, 3.2, 3.3 and 3.4¹³⁷ we first describe the various jet algorithms, groomers, ¹³⁸ taggers and other substructure variables used in these¹³⁹ studies, and then in Section 3.5 list which observables are considered in each section of this report, and the¹⁴¹ exact settings of the parameters used.

3.1 Jet Clustering Algorithms

Jet clustering: Jets were clustered using sequentiah₄₇ jet clustering algorithms[REF]implemented in FAST-₁₄₈

JET 3.0.3. Final state particles i, j are assigned a mutual distance d_{ij} and a distance to the beam, d_{iB} . The particle pair with smallest d_{ij} are recombined and the algorithm repeated until the smallest distance is instead the distance to the beam, d_{iB} , in which case i is set aside and labelled as a jet. The distance metrics are defined

$$d_{ij} = \min(p_{Ti}^{2\gamma}, p_{Tj}^{2\gamma}) \frac{\Delta R_{ij}^2}{R^2}, \tag{1}$$

$$d_{i\mathrm{B}} = p_{T_i}^{2\gamma},\tag{2}$$

where $\Delta R_{ij}^2 = (\Delta \eta)^2 + (\Delta \phi)^2$. In this analysis, we use the anti- k_t algorithm $(\gamma = -1)$, the Cambridge/Aachen (C/A) algorithm $(\gamma = 0)[\mathbf{REF}]$, and the k_t algorithm $(\gamma = 1)[\mathbf{REF}]$, each of which has varying sensitivity to soft radiation in defining the jet.

Qjets: We also perform non-deterministic jet clustering [REF]. Instead of always clustering the particle pair with smallest distance d_{ij} , the pair selected for combination is chosen probabilistically according to a measure

$$P_{ij} \propto e^{-\alpha (d_{ij} - d_{\min})/d_{\min}},\tag{3}$$

where $d_{\rm min}$ is the minimum distance for the usual jet clustering algorithm at a particular step. This leads to a different cluster sequence for the jet each time the Qjet algorithm is used, and consequently different substructure properties. The parameter α is called the rigidity and is used to control how sharply peaked the probability distribution is around the usual, deterministic value. The Qjets method uses statistical analysis of the resulting distributions to extract more information from the jet than can be found in the usual cluster sequence. We use $\alpha=0.1$ and 25 trees per event for all the studies presented here.

3.2 Jet Grooming Algorithms

Pruning: Given a jet, re-cluster the constituents using the C/A algorithm. At each step, proceed with the merger as usual unless both

$$\frac{\min(p_{Ti}, p_{Tj})}{p_{Tij}} < z_{\text{cut}} \text{ and } \Delta R_{ij} > \frac{2m_j}{p_{Tj}} R_{\text{cut}},$$
 (4)₁₇₈

in which case the merger is vetoed and the softer branch¹⁸⁰ tagged. If de-clustering continues until only one branch discarded. The default parameters used for pruning [**REF**] inremains, the jet is untagged. In this study we use by this study are $z_{\text{cut}} = 0.1$ and $R_{\text{cut}} = 0.5$. One advan-¹⁸² default $\mu = 1.0$ and $y_{\text{cut}} = 0.1$.

tage of pruning is that the thresholds used to veto soft,¹⁸³ wide-angle radiation scale with the jet kinematics, and¹⁸⁴ Johns Hopkins Tagger: Re-cluster the jet using the over a wide range of momenta.

C/A algorithm. The jet is iteratively de-clustered, and at each step the softer prong is discarded if its p_{T} is

Trimming: Given a jet, re-cluster the constituents into subjets of radius R_{trim} with the k_t algorithm. Discardae all subjets i with

$$p_{Ti} < f_{\text{cut}} \, p_{TJ}.$$
 (5)₁₉₂

191

219

The default parameters used for trimming [REF] in this study are $R_{\rm trim}=0.2$ and $f_{\rm cut}=0.03$.

Filtering: [REF] Given a jet, re-cluster the constituents into subjets of radius $R_{\rm filt}$ with the C/A algorithm. Redefine the jet to consist of only the hardest N subjets, where N is determined by the final state topology and is typically one more than the number of hard prongs in the resonance decay (to include the leading final-state gluon emission). ED: Do we actually use filtering as described here anywhere? (BS: Yes, it is used in the HEPTopTagger.)

Soft drop: Given a jet, re-cluster all of the constituents using the C/A algorithm. Iteratively undo the last stage of the C/A clustering from j into subjets j_1 , j_2 . If

$$\frac{\min(p_{T1}, p_{T2})}{p_{T1} + p_{T2}} < z_{\text{cut}} \left(\frac{\Delta R_{12}}{R}\right)^{\beta}, \tag{6}_{211}$$

discard the softer subjet and repeat. Otherwise, take j^{213} to be the final soft-drop jet[REF]. Soft drop has two²¹⁴ input parameters, the angular exponent β and the soft-²¹⁵ drop scale $z_{\rm cut}$, with default value $z_{\rm cut} = 0.1$. ED: Soft-²¹⁶ drop actually functions as a tagger when $\beta = -1^{217}$

3.3 Jet Tagging Algorithms

Modified Mass Drop Tagger: Given a jet, re-cluster₂₂₂ all of the constituents using the C/A algorithm. Itera-₂₂₃ tively undo the last stage of the C/A clustering from j_{224}

into subjets j_1 , j_2 with $m_{j_1} > m_{j_2}$. If either

$$m_{j_1} > \mu \, m_j \text{ or } \frac{\min(p_{T1}^2, p_{T2}^2)}{m_j^2} \, \Delta R_{12}^2 < y_{\text{cut}},$$
 (7)

then discard the branch with the smaller transverse mass $m_T = \sqrt{m_i^2 + p_{Ti}^2}$, and re-define j as the branch with the larger transverse mass. Otherwise, the jet is tagged. If de-clustering continues until only one branch aremains, the jet is untagged. In this study we use by default $\mu = 1.0$ and $y_{\rm cut} = 0.1$.

Johns Hopkins Tagger: Re-cluster the jet using the C/A algorithm. The jet is iteratively de-clustered, and at each step the softer prong is discarded if its p_T is less than $\delta_p p_{\mathrm{T\,jet}}$. This continues until both prongs are harder than the $p_{\rm T}$ threshold, both prongs are softer than the $p_{\rm T}$ threshold, or if they are too close ($|\Delta \eta_{ij}|$ + $|\Delta\phi_{ij}|<\delta_R$); the jet is rejected if either of the latter conditions apply. If both are harder than the $p_{\rm T}$ threshold, the same procedure is applied to each: this results in 2, 3, or 4 subjets. If there exist 3 or 4 subjets, then the jet is accepted: the top candidate is the sum of the subjets, and W candidate is the pair of subjets closest to the W mass. The output of the tagger is m_t , m_W , and θ_h , a helicity angle defined as the angle, measured in the rest frame of the W candidate, between the top direction and one of the W decay products. The two free input parameters of the John Hopkins tagger in this study are δ_p and δ_R , defined above.

HEPTopTagger: Re-cluster the jet using the C/A algorithm. The jet is iteratively de-clustered, and at each step the softer prong is discarded if $m_1/m_{12} > \mu$ (there is not a significant mass drop). Otherwise, both prongs are kept. This continues until a prong has a mass $m_i < m$, at which point it is added to the list of subjets. Filter the jet using $R_{\rm filt} = \min(0.3, \Delta R_{ij})$, keeping the five hardest subjets (where ΔR_{ij} is the distance between the two hardest subjets). Select the three subjets whose invariant mass is closest to m_t . The output of the tagger is m_t , m_W , and θ_h , a helicity angle defined as the angle, measured in the rest frame of the W candidate, between the top direction and one of the W decay products. The two free input parameters of the HEP-TopTagger in this study are m and μ , defined above.

Top Tagging with Pruning: For comparison with the other top taggers, we add a W reconstruction step to the trimming algorithm described above. A W candidate is found as follows: if there are two subjets, the highest-mass subjet is the W candidate (because the W prongs end up clustered in the same subjet); if there

247

248

249

are three subjets, the two subjets with the smallest in-251 variant mass comprise the W candidate. In the case of 252only one subjet, no W is reconstructed.

Top Tagging with Trimming: For comparison with the other top taggers, we add a W reconstruction step to the trimming algorithm described above. A W candidate is found as follows: if there are two subjets, the highest-mass subjet is the W candidate (because the W prongs end up clustered in the same subjet); if there are three subjets, the two subjets with the smallest invariant mass comprise the W candidate. In the case of only one subjet, no W is reconstructed.

3.4 Other Jet Substructure Observables

Qjet mass volatility: As described above, Qjet algorithms re-cluster the same jet non-deterministically to obtain a collection of interpretations of the jet. For each jet interpretation, the pruned jet mass is computed with the default pruning parameters. The mass volatility, Γ_{Oiet} , is defined as

$$\Gamma_{\text{Qjet}} = \frac{\sqrt{\langle m_J^2 \rangle - \langle m_J \rangle^2}}{\langle m_J \rangle},$$
(8)

where averages are computed over the Qjet interpreta- $_{\scriptscriptstyle{259}}$ tions.

N-subjettiness: N-subjettiness[REF] quantifies how $\frac{1}{262}$ well the radiation in the jet is aligned along N direc- 263 tions. To compute N-subjettiness, $\tau_N^{(\beta)}$, one must first identify N axes within the jet. Then,

$$\tau_N = \frac{1}{d_0} \sum_{i} p_{T_i} \min\left(\Delta R_{1i}^{\beta}, \dots, \Delta R_{Ni}^{\beta}\right), \tag{9}$$

where distances are between particles i in the jet and₂₆₈

$$d_0 = \sum_i p_{T_i} R^{\beta} \tag{10}_{271}^{270}$$

and R is the jet clustering radius. The exponent β is₂₇₃ a free parameter. There is also some choice in how the₂₇₄ axes used to compute N-subjettiness are determined $_{.275}$ The optimal configuration of axes is the one that min-276 imizes N-subjettiness; recently, it was shown that the₂₇₇ "winner-takes-all" (WTA) axes can be easily computed₂₇₈ and have superior performance compared to other min-279 imization techniques [REF]. We use both the WTA and₂₈₀ one-pass k_t optimization axes in our analyses.

A more powerful discriminant is often the ratio,

$$\tau_{N,N-1} \equiv \frac{\tau_N}{\tau_{N-1}}.\tag{11}_{283}^{^{282}}$$

While this is not an infrared-collinear (IRC) safe observable, it is calculable [REF] and can be made IRC safe with a loose lower cut on τ_{N-1} .

Energy correlation functions: The transverse momentum version of the energy correlation functions are defined as $[\mathbf{REF}]$:

$$ECF(N,\beta) = \sum_{i_1 < i_2 < \dots < i_N \in j} \left(\prod_{a=1}^N p_{Ti_a} \right) \left(\prod_{b=1}^{N-1} \prod_{c=b+1}^N \Delta R_{i_b i_c} \right)^{\beta},$$
(12)

where i is a particle inside the jet. It is preferable to work in terms of dimensionless quantities, particularly the energy correlation function double ratio:

$$C_N^{(\beta)} = \frac{\text{ECF}(N+1,\beta) \, \text{ECF}(N-1,\beta)}{\text{ECF}(N,\beta)^2}.$$
 (13)

This observable measures higher-order radiation from leading-order substructure.

3.5 Observables for Each Analysis

Quark/gluon discrimination:

- The ungroomed jet mass, m. 1-subjettiness, τ_1^{β} with $\beta=1,\,2.$ The N-subjettiness axes are computed using one-pass k_t axis optimiza-
- 1-point energy correlation functions, $C_1^{(\beta)}$ with $\beta =$
- The pruned Qjet mass volatility, Γ_{Qjet} .
- The number of constituents (N_{constits}).

W vs. gluon discrimination:

- The ungroomed, trimmed (m_{trim}) , and pruned (m_{prun}) jet masses.
- The mass output from the modified mass drop tagger (m_{mmdt}) .
- The soft drop mass with $\beta = -1, 2 (m_{sd})$.
- 2-point energy correlation function ratio $C_2^{\beta=1}$ (we also studied $\beta = 2$ but did not show its results be-
- cause it showed poor discrimination power). N-subjettiness ratio τ_2/τ_1 with $\beta=1$ $(\tau_{21}^{\beta=1})$ and with axes computed using one-pass k_t axis optimization (we also studied $\beta = 2$ but did not show its results because it showed poor discrimination power).
- The pruned Qjet mass volatility.

Top vs. QCD discrimination:

- The ungroomed jet mass.
- The HEPTopTagger and the Johns Hopkins tagger.

- 2-point energy correlation function ratios $C_2^{\beta=1}$ and $C_2^{\beta=1}$ and $C_2^{\beta=1}$.
 - The pruned Qjet mass volatility, Γ_{Qjet} .

4 Multivariate Analysis Techniques

Multivariate techniques are used to combine vari-³⁴⁰ ables into an optimal discriminant. In all cases vari-³⁴¹ ables are combined using a boosted decision tree (BDT) as implemented in the TMVA package [?]. We use the BDT implementation including gradient boost. An ex-³⁴² ample of the BDT settings are as follows:

- 343 NTrees=1000298 BoostType=Grad 299 Shrinkage=0.1 300 UseBaggedGrad=F 301 nCuts=10000MaxDepth=3 348 303 UseYesNoLeaf=F 304 nEventsMin=200 305
 - Exact parameter values are chosen to best reduce the³⁵¹ effect of overtraining. **ED:** Can we describe a bit³⁵² more the tests we do to ensure that we are not³⁵³ suffering from overtraining?

5 Quark-Gluon Discrimination

In this section, we examine the differences between quarkand gluon-initiated jets in terms of substructure variables, and to determine to what extent these variables₃₆₁ are correlated. Along the way, we provide some theoretical understanding of these observables and their performance. The motivation for these studies comes not $_{364}$ only from the desire to "tag" a jet as originating from a $_{365}^{\circ}$ quark or gluon, but also to improve our understanding $_{\!{}_{\!{}_{366}}}$ of the quark and gluon components of the QCD backgrounds relative to boosted resonances. While recent studies have suggested that quark/gluon tagging effi- $\frac{1}{369}$ ciencies depend highly on the Monte Carlo generator $_{_{370}}^{^{^{\prime\prime}}}$ used [REF], we are more interested in understanding $_{\!_{371}}$ the scaling performance with p_T and R, and the correlations between observables, which are expected to be 373 treated consistently within a single shower scheme.

5.1 Methodology

These studies use the qq and gg MC samples, described previously in Section 2. The showered events were clus-379

tered with FASTJET 3.03[**REF**] using the anti- $k_{\rm T}$ algorithm[**REF**] with jet radii of $R=0.4,\,0.8,\,1.2.$ In both signal (quark) and background (gluon) samples, an upper and lower cut on the leading jet p_T is applied after showering/clustering, to ensure similar p_T spectra for signal and background in each p_T bin. The bins in leading jet p_T that are considered are 300-400 GeV, 500-600 GeV, 1.0-1.1 TeV, for the 300-400 GeV, 500-600 GeV, 1.0-1.1 TeV parton p_T slices respectively. Various jet grooming approaches are applied to the jets, as described in Section 3.4. Only leading and subleading jets in each sample are used.

5.2 Single Variable Discrimination

355

356

Figure 2 shows the mass of jets in the quark and gluon samples when using different groomers, and the ungroomed jet mass, for jets with R=0.8 and in the $p_T=500-600$ GeV bin. Qualitatively, the application of grooming shifts the mass distributions towards lower values when compared to the ungroomed mass, as expected. No clear gain in discrimination can be seen, and for certain grooming parameters, such as the use of soft drop with $\beta=-1$ a clear loss in discrimination power is observed; this is because the soft-drop condition for $\beta=-1$ discards collinear radiation, and the differences between quarks and gluons are manifest in the collinear structure (spin, splitting functions, etc.).

The quark and gluon distributions of different substructure variables are shown in Figure 3. Among those considered, one can see by eye that n_{constits} provides the highest separation power, followed by $C_1^{\beta=0}$ and $C_1^{\beta=1}$, as was also found by the CMS and ATLAS Collaborations[**REF**].

To more quantitatively study the power of each observable as a discriminator for quark/gluon tagging, ROC curves are built by scanning each distribution and plotting the background efficiency (to select gluon jets) vs. the signal efficiency (to select quark jets). Figure 4 shows these ROC curves for all of the substructure variables shown in Figure 3, along with the ungroomed mass, representing the best performing mass variable, for R=0.4, 0.8 and 1.2 jets in the $p_T = 300 - 400 \text{ GeV}$ bin. In addition, the ROC curve for a tagger built from a BDT combination of all the variables (see Section 4) is shown. Clearly, n_{constits} is the best performing variable for all Rs, even though $C_1^{\beta=0}$ is close, particularly for R=0.8. Most other variables have similar performance, except Γ_{Qjet} , which shows significantly worse discrimination (this may be due to our choice of rigidity $\alpha = 0.1$, with other studies suggesting that a smaller value, such as $\alpha = 0.01$, produces better results [**REF**]).

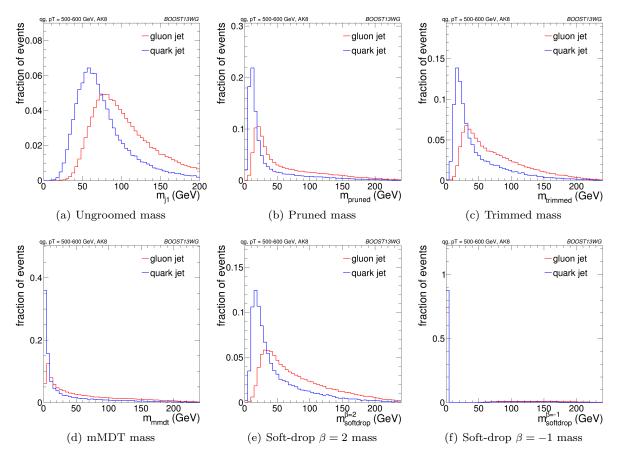

Fig. 2 Comparisons of ungroomed and groomed quark and gluon mass distributions for leading jets in the $p_T = 500 - 600$ GeV bin using the anti- $k_{\rm T}$ R=0.8 algorithm.

The combination of all variables shows somewhat better₄₀₂ discrimination.

396

398

399

400

401

We now examine how performance of masses and substructure observables changes with p_T and R. For $_{405}$ jet masses, few variations are observed as the radius parameter of the jet reconstruction is increased in the two $_{407}$ highest p_T bins; this is because the radiation is more $_{408}$ collimated and the dependence on R is consequently $_{409}$ smaller. However, for the 300-400 GeV bin, the use of $_{410}$ small-R jets produces a shift in the mass distributions $_{411}$ towards lower values, so that large-R jet masses are $_{412}$ more stable with p_T and small-R jet masses are smaller $_{413}$ at low- p_T as expected from the spatial constraints im- $_{414}$ posed by the R parameter. These statements are ex- $_{415}$ plored more quantitatively later in this section. (BS: $_{416}$ Do we have plots for this?)

The evolution of some of the substructure variable 418 distributions with p_T and R is less trivial than for the 419 jet masses. In particular, changing the R parameter at 420 high p_T changes significantly the C_a^{β} for $\beta>0$ and 421 the $n_{\rm constits}$ distributions, while leaving all other distri-422 butions qualitatively unchanged. This is illustrated in 423

Figure 5 for $\beta = 0$ and $\beta = 1$ using a = 1 in both cases for jets with $p_T = 1.0 - 1.1$ TeV.

The shift towards lower values with changing R is evident for the $C_1^{\beta=1}$ distributions, while the stability of $C_1^{\beta=0}$ can also be observed. These features are present in all p_T bins studied, but are even more pronounced for lower p_T bins. The shape of the Q-jet volatility distribution shows some non-trivial shape that deserves some explanation. Two peaks are observed, one at low volatility values and one at mid-volatility. These peaks are generated by two somewhat distinct populations. The high volatility peak arises from jets that get their mass primarily from soft (and sometimes wide-angle) emissions. The removal of some of the constituents when building Q-jets thus changes the mass significantly, increasing the volatility. The lower volatility peak corresponds to jets for which mass is generated by a hard emission, which makes the fraction of Q-jets that change the mass significantly to be smaller. Since the probability of a hard emission is proportional to the colour charge (squared), the volatility peak is higher for gluon jets by about the colour factor C_A/C_F .

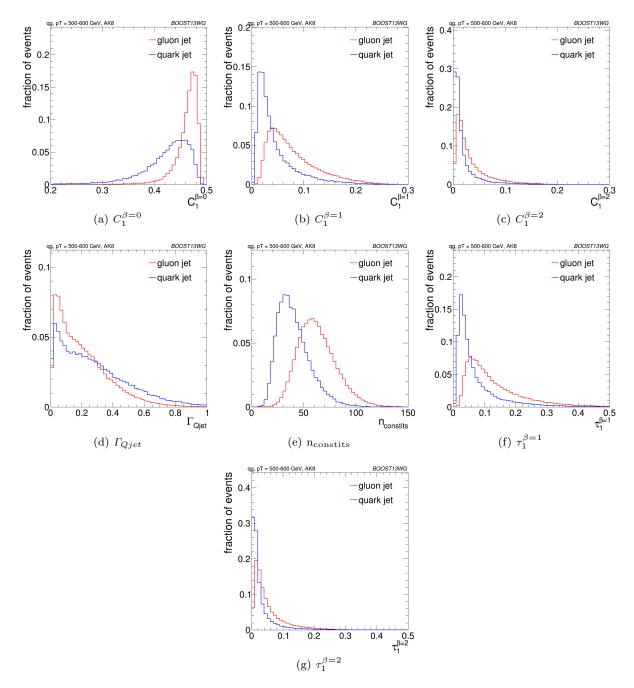

Fig. 3 Comparisons of quark and gluon distributions of different substructure variables for leading jets in the $p_T = 500 - 600$ GeV bin using the anti- k_T R=0.8 algorithm.

In summary, the overall discriminating power be- $_{432}$ tween quarks and gluons decreases with increasing R due to the reduction in the amount of out-of-cone radi- $_{433}$ ation differences and and increased contamination from $_{434}$ the underlying event (**BS: is this ok?**). The broad per- $_{435}$ formance features discussed for this p_T bin also apply $_{436}$ to the higher p_T bins. These is further quantified in the $_{437}$ next section.

5.3 Combined Performance and Correlations

The quark/gluon tagging performance can be further improved over cuts on single observables by combining multiple observables in a BDT; due to the challenging nature of q/g-tagging, any improvement in performance with multivariable techniques could be critical for certain analyses, and the improvement could be more substantial in data than the marginal benefit

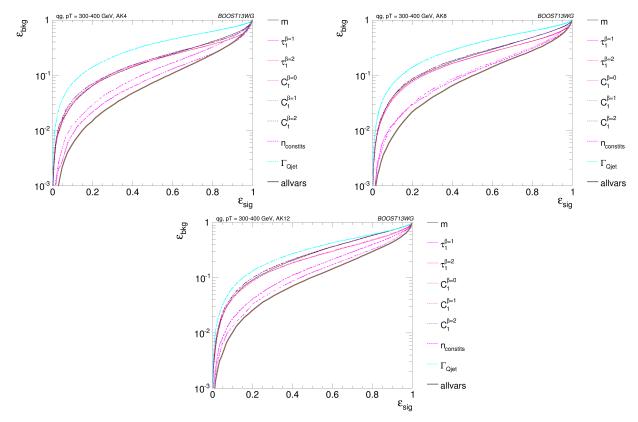

Fig. 4 The ROC curve for all single variables considered for quark-gluon discrimination in the p_T 300-400 GeV bin using the anti- k_T R=0.4, 0.8 and 1.2 algorithm.**ED**: Hard to tell the lines on the plots apart

found in MC and shown in Fig. 4. Furthermore, insight₄₆₄ can be gained into the features allowing for quark/gluon₄₆₅ discrimination if the origin of the improvement is un- $_{466}$ derstood. To quantitatively study this improvement, we₄₆₇ build quark/gluon taggers from every pair-wise combi- $_{468}$ nation of variables studied in the previous section for₄₆₉ comparison with the all-variable combination.

In order to quantitatively study the value of each⁴⁷¹ variable for quark/gluon tagging, we study the gluon⁴⁷² rejection, defined as $1/\epsilon_{\rm gluon}$, at a fixed quark selection⁴⁷³ efficiency of 50% using jets with $p_T = 1 - 1.1$ TeV and 474 for different R parameters. Figure 6 shows the gluon⁴⁷⁵ rejection for each pair-wise combination. The pair-wise₄₇₆ gluon rejection at 50% quark efficiency can be compared 477 to the single-variable values shown along the diagonal.478 The gluon rejection for the BDT all-variable combina-479 tion is also shown on the bottom right of each plot. As480 already observed in the previous section, n_{constits} is the most powerful single variable and $C_1^{(\beta=0)}$ follows closely.482 However, the gains are largely correlated; the combined $_{483}$ performance of $n_{\rm constits}$ and $C_1^{(\beta=0)}$ is generally poorer₄₈₄ than combinations of $n_{\rm constits}$ with other jet substruc-485 ture observables, such as au_1 . Interestingly, in spite of the high correlation between $n_{\rm constits}$ and $C_1^{(\beta=0)}$, the two-487

variable combinations of $n_{\rm constits}$ generally fare worse than two-variable combinations with $C_1^{(\beta=0)}$. In particular, the combinations of $\tau_1^{\beta=1}$ or $C_1^{(\beta=1)}$ with $n_{\rm constits}$ are capable of getting very close to the rejection achievable through the use of all variables for R=0.4 and R=0.8.

Tagger performance is generally better at small R. The overall loss in performance with increasing R can be seen in most single variables we study; this is expected, since more of the parton radiation is captured in the jet and more contamination from underlying event occurs, suppressing the differences between q/g jets. The principal exceptions are $C_1^{(\beta=0)}$ and the Q-jet mass volatility, which are both quite resilient to increasing R. For $C_1^{(\beta=0)}$, this is due to the fact that the exponent on ΔR is zero, and so soft radiation at the periphery of the jet does not substantially change the distribution; as a result, the performance is largely independent of R. Similarly, the soft radiation distant from the jet centre will be vetoed during pruning regardless of the cluster sequence, and so the R-dependence of Γ_{Qjet} is not significant. (BS: Check my logic?) Their combination, however, does perform slightly worse at larger R. (BS: I don't understand this, but it is a $\sim 10\%$ ef-

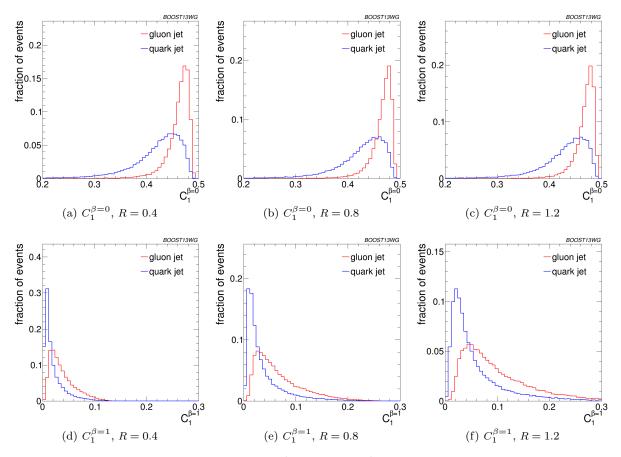

Fig. 5 Comparisons of quark and gluon distributions of $C_1^{\beta=0}$ (top) and $C_1^{\beta=1}$ (bottom) for leading jets in the $p_T = 1-1.1$ TeV bin using the anti- k_T algorithm with R = 0.4, 0.8 and 1.2.

fect, so maybe not too significant?). By contrast, $\tau_1^{(\beta=2)}$ and $C_1^{(\beta=2)}$ are particularly sensitive to increasing R since, for $\beta=2$, large-angle emissions are given a larger weight.

These observations are qualitatively similar across all ranges of p_T . Quantitatively, however, there is a loss of rejection power for the taggers made of a combination of variables as the p_T decreases. This can be observed in Fig. 7 for anti- $k_{\rm T}$ R=0.4 jets of different p_T s. Clearly, most single variables retain their gluon rejection potential at lower p_T . However, when combined with other variables, the highest performing pairwise combinations lose ground with respect to other pairwise combinations. This is also reflected in the rejection of the tagger that uses a combination of all variables, which is lower at lower p_T s. [do we understand this?] (BS: This is a bit of a guess, but could it be that there is typically less radiation for low p_T , and so you're more sensitive to fluctuations; since you have less access to information, combinations of observables perform less well than at high p_T .)

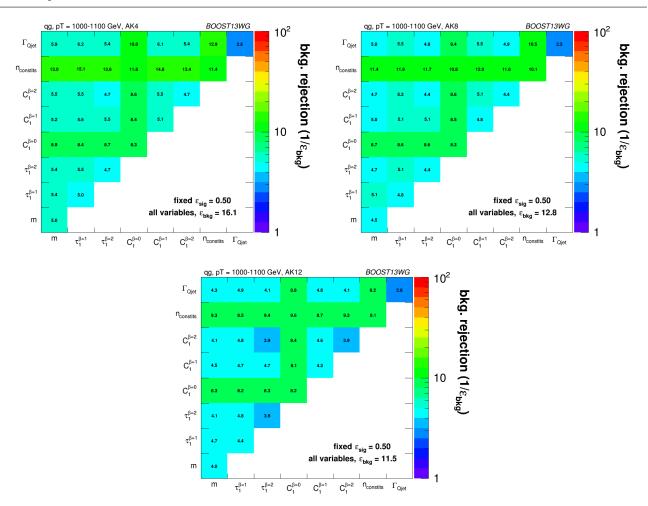

Fig. 6 Gluon rejection defined as $1/\epsilon_{\rm gluon}$ when using each 2-variable combination as a tagger with 50% acceptance for quark jets. Results are shown for jets with $p_T = 1 - 1.1$ TeV and for (left) R = 0.4; (centre) R = 0.8; (right) R = 1.2. The rejection obtained with a tagger that uses all variables is also shown in the plots.

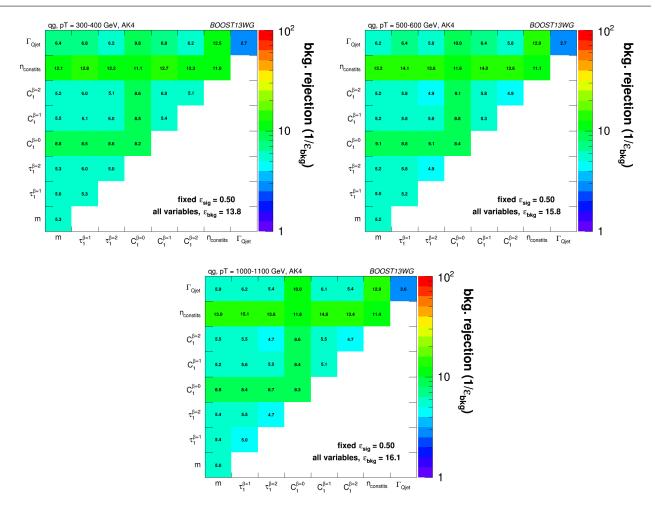

Fig. 7 Gluon rejection defined as $1/\epsilon_{\rm gluon}$ when using each 2-variable combination as a tagger with 50% acceptance for quark jets. Results are shown for R=0.4 jets with $p_T=300-400$ GeV, $p_T=500-600$ GeV and $p_T=1-1.1$ TeV. The rejection obtained with a tagger that uses all variables is also shown in the plots.

These studies use the WW samples as signal and the dijet gg as background, described previously in Section 2. Whilst only gluonic backgrounds are explored here, the conclusions as to the dependence of the performance and correlations on the jet boost and radius have been verified to hold also for qq backgrounds. **ED: To be checked!**

As in the q/g tagging studies, the showered events were clustered with FASTJET 3.03 using the anti- $k_{\rm T}$ algorithm with jet radii of $R=0.4,\,0.8,\,1.2.$ In both signal and background samples, an upper and lower cut on the leading jet p_T is applied after showering/clustering, to ensure similar p_T spectra for signal and background in each p_T bin. The bins in leading jet p_T that are considered are 300-400 GeV, 500-600 GeV, 1.0-1.1 TeV, for the 300-400 GeV, 500-600 GeV, 1.0-1.1 TeV parton p_T slices respectively. The jets then have various grooming approaches applied and substructure observables reconstructed as described in Section 3.5. (ED: Better if some of the information from Section 3.5 is brought into this section to avoid this backreferencing?)

6.2 Single Variable Performance

In this section we will explore the performance of the various groomed jet mass and substructure variables in terms of discriminating signal and background, and how this performance changes depending on the kinematic bin and jet radius considered.

Figure 8 the compares the signal and background in terms of the different groomed masses explored for the anti- $k_{\rm T}$ R=0.8 algorithm in the p_T 500-600 bin. One can clearly see that in terms of separating signal and background the groomed masses will be significantly more performant than the ungroomed anti- $k_{\rm T}$ R=0.8 mass. Figure 9 compares signal and background in the different substructure variables explored for the same jet radius and kinematic bin.

Figures 10, 11 and 12 show the single variable ROC curves compared to the ROC curve for a BDT combination of all the variables (labelled "allvars"), for each of the anti- $k_{\rm T}$ distance parameters considered in each of the kinematic bins. One can see that, in all cases, the "allvars" option is considerably better performant than any of the individual single variables considered, indicating that there is considerable complementarity

In this section, we study the discrimination of a boosted₅₅₈ hadronically decaying W signal against a gluon back-559 ground, comparing the performance of various groomed₅₆₀ jet masses, substructure variables, and BDT combina-561 tions of groomed mass and substructure. We produce562 ROC curves that elucidate the performance of the vari-563 ous groomed mass and substructure variables. A ranges64 of different distance parameters R for the anti- $k_{\rm T}$ jets 55 algorithm are explored, as well as a variety of kine-566 matic regimes (lead jet p_T 300-400 GeV, 500-600 GeV, 1.0-1.1 TeV). This allows us to determine the perfor-568 mance of observables as a function of jet radius and jets69 boost, and to see where different approaches may break570 down. The groomed mass and substructure variables₅₇₁ are then combined in a BDT as described in Section 4,572 and the performance of the resulting BDT discriminants73 explored through ROC curves to understand the degrees74

radius and momenta.

Although the ROC curves give all the relevant information, it is hard to compare performance quanti-598 tatively. In Figures 13, 14 and 15 are shown matrices599 which give the background rejection for a signal effi-600 ciency of 70% when two variables (that on the x-axis601 and that on the y-axis) are combined in a BDT. These602 are shown separately for each p_T bin and jet radius603 considered. In the final column of these plots are shown604 the background rejection performance for three-variable605 BDT combinations of $m_{sd}^{\beta=2} + C_2^{\beta=1} + X$. These results606 will be discussed later in Section 6.3.3. The diagonal of607 these plots correspond to the background rejections for608 a single variable BDT, and can thus be examined to get609 a quantitative measure of the individual single variable610 performance, and to study how this changes with jet611

One can see that in general the most performant₆₁₄ single variables are the groomed masses. However, in₆₁₅ certain kinematic bins and for certain jet radii, $C_2^{\beta=1}$ ₆₁₆

has a background rejection that is comparable to or better than the groomed masses.

By comparing Figures 13(a), 14(a) and 15(b), we can see how the background rejection performance evolves as we increase momenta whilst keeping the jet radius fixed to R=0.8. Similarly, by comparing Figures 13(b), 14(b) and 15(c) we can see how performance evolves with p_T for R=1.2. For both R=0.8 and R=1.2 the background rejection power of the groomed masses increases with increasing p_T , with a factor 1.5-2.5 increase in rejection in going from the 300-400~GeV to 1.0-1.1~TeV bins. ED: Add some of the 1-D plots comparing signal and bkgd in the different masses and pT bins here? However, the $C_2^{\beta=1}$, Γ_{Qjet} and $\tau_{21}^{\beta=1}$ substructure variables behave somewhat differently. The background rejection power of the Γ_{Qjet} and $\tau_{21}^{\beta=1}$ variables both decrease with increasing p_T , by up to a factor two in going from the 300-400 GeV to 1.0-1.1 TeV bins. Conversely the rejection power of $C_2^{\beta=1}$ dramatically increases with increasing p_T for R=0.8, but does not improve with p_T for the larger jet radius R=1.2. **ED**:

Can we explain this? Again, should we add some of the 1-D plots?

and 15 we can see how the background rejection perfor-671 mance depends on jet radius within the same p_T bin. 572 To within $\sim 25\%$, the background rejection power of $_{673}$ the groomed masses remains constant with respect to 674 the jet radius. However, we again see rather differenters behaviour for the substructure variables. In all p_T bins considered the most performant substructure variable, 676 $C_2^{\beta=1}$, performs best for an anti- $k_{\rm T}$ distance parameter of R=0.8. The performance of this variable is dra_{-677} factor seven worse background rejection in the $1.0-1.1_{679}$ TeV bin), and substantially worse for R=0.4. For the 680 other jet substructure variables considered, Γ_{Qjet} and $_{_{681}}$ $au_{21}^{\beta=1}$, their background rejection power also reduces for au_{682} larger jet radius, but not to the same extent. **ED: In-**₆₈₃ sert some nice discussion/explanation of why jet₆₈₄ substructure power generally gets worse as we go to large jet radius, but groomed mass performance does not. Probably need the 1-D figures, say

6.3 Combined Performance

The off-diagonal entries in Figures 13, 14 and 15 can⁶⁹² be used to compare the performance of different BDT₆₉₃ two-variable combinations, and see how this varies as 694 a function of p_T and R. By comparing the background⁶⁹⁵ rejection achieved for the two-variable combinations to 696 the background rejection of the "all variables" BDT.697 one can understand how much more discrimination is 698 possible by adding further variables to the two-variable⁶⁹⁹

One can see that in general the most powerful two-701 variable combinations involve a groomed mass and and non-mass substructure variable $(C_2^{\beta=1},\,\Gamma_{Qjet}\text{ or }\tau_{21}^{\beta=1})$.703 Two-variable combinations of the substructure variables⁶⁴ are not powerful in comparison. Which particular mass⁷⁰⁵ + substructure variable combination is the most pow-706 erful depends strongly on the p_T and R of the jet, as₇₀₇ discussed in the sections that follow.

There is also modest improvement in the background on rejection when different groomed masses are combined,710 compared to the single variable groomed mass perfor-711 mance, indicating that there is complementary informa-712 tion between the different groomed masses. In addition,713 there is an improvement in the background rejection₇₁₄ when the groomed masses are combined with the un-715 groomed mass, indicating that grooming removes some₇₁₆ useful discriminatory information from the jet. These₇₁₇ observations are explored further in the section below.718

Generally one can see that the R=0.8 jets offer the best two-variable combined performance in all p_T bins By comparing the individual sub-figures of Figures 13, 14explored here. This is despite the fact that in the highest 1.0-1.1 GeV p_T bin the average separation of the quarks from the W decay is much smaller than 0.8, and well within 0.4. This conclusion could of course be susceptible to pile-up, which is not considered in this study.

$6.3.1 \; Mass + Substructure \; Performance$

As already noted, the largest background rejection at 70% signal efficiency are in general achieved using those two variable BDT combinations which involve a groomed mass and a non-mass substructure variable. For both R=0.8 and R=1.2 jets, the rejection power of these two variable combinations increases substantially with increasing p_T , at least within the p_T range considered

For a jet radius of R=0.8, across the full p_T range considered, the groomed mass + substructure variable combinations with the largest background rejection are those which involve $C_2^{\beta=1}$. For example, in combination with $m_{sd}^{\beta=2}$, this produces a five-, eight- and fifteen-fold increase in background rejection compared to using the groomed mass alone. In Figure 16 the low degree of correlation between $m_{sd}^{\beta=2}$ versus $C_2^{\beta=1}$ that leads to these large improvements in background rejection can be seen. One can also see that what little correlation exists is rather non-linear in nature, changing from a negative to a positive correlation as a function of the groomed mass, something which helps to improve the background rejection in the region of the W mass peak.

However, when we switch to a jet radius of R=1.2 the picture for $C_2^{\beta=1}$ combinations changes dramatically. These become significantly less powerful, and the most powerful variable in groomed mass combinations becomes $\tau_{21}^{\beta=1}$ for all jet p_T considered. Figure 17 shows the correlation between $m_{sd}^{\beta=2}$ and $C_2^{\beta=1}$ in the p_T 1.0 - 1.2 TeV bin for the various jet radii considered. Figure 18 is the equivalent set of distributions for $m_{sd}^{\beta=2}$ and $\tau_{21}^{\beta=1}$. One can see from Figure 17 that, due to the sensitivity of the observable to to soft, wide-angle radiation, as the jet radius increases $C_2^{\beta=1}$ increases and becomes more and more smeared out for both signal and background, leading to worse discrimination power. This does not happen to the same extent for $\tau_{21}^{\beta=1}$. We can see from Figure 18 that the negative correlation between $m_{sd}^{\beta=2}$ and $\tau_{21}^{\beta=1}$ that is clearly visible for R=0.4 decreases for larger jet radius, such that the groomed mass and substructure variable are far less correlated and $\tau_{21}^{\beta=1}$ offers improved discrimination within a $m_{sd}^{\beta=2}$

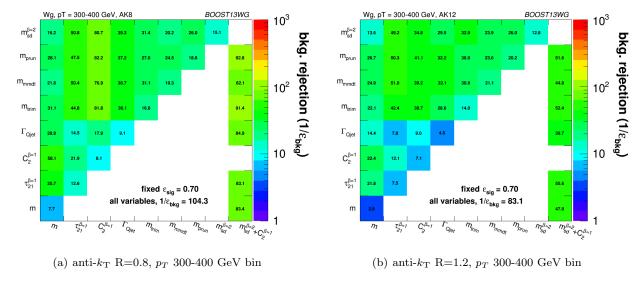

Fig. 13 The background rejection for a fixed signal efficiency (70%) of each BDT combination of each pair of variables considered, in the p_T 300-400 GeV bin using the anti- k_T R=0.8 algorithm and R=1.2 algorithm. Also shown is the background rejection for a BDT combination of all of the variables considered.

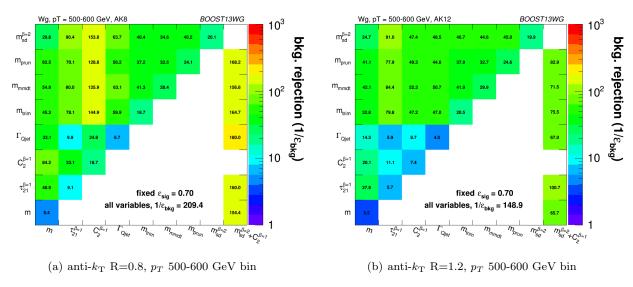

Fig. 14 The background rejection for a fixed signal efficiency (70%) of each BDT combination of each pair of variables considered, in the p_T 500-600 GeV bin using the anti- k_T R=0.8 algorithm and R=1.2 algorithm. Also shown is the background rejection for a BDT combination of all of the variables considered.

6.3.2 Mass + Mass Performance

719

721

722

723

724

725

726

727

728

The different groomed masses and the ungroomed mass $_{731}$ are of course not fully correlated, and thus one can al $_{732}$ ways see some kind of improvement in the background $_{733}$ rejection (relative to the single mass performance) when $_{734}$ two different mass variables are combined in the BDT. $_{735}$ However, in some cases the improvement can be dra $_{736}$ matic, particularly at higher p_T , and particularly for $_{737}$ combinations with the ungroomed mass. For example, $_{738}$ in Figure 15 we can see that in the p_T 1.0-1.1 TeV bin

the combination of pruned mass with ungroomed mass produces a greater than eight-fold improvement in the background rejection for R=0.4 jets, a greater than five-fold improvement for R=0.8 jets, and a factor \sim two improvement for R=1.2 jets. A similar behaviour can be seen for mMDT mass. In Figures 19, 20 and 21 is shown the 2-D correlation plots of the pruned mass versus the ungroomed mass separately for the WW signal and gg background samples in the p_T 1.0-1.1 TeV bin, for the various jet radii considered. For comparison, the corre-

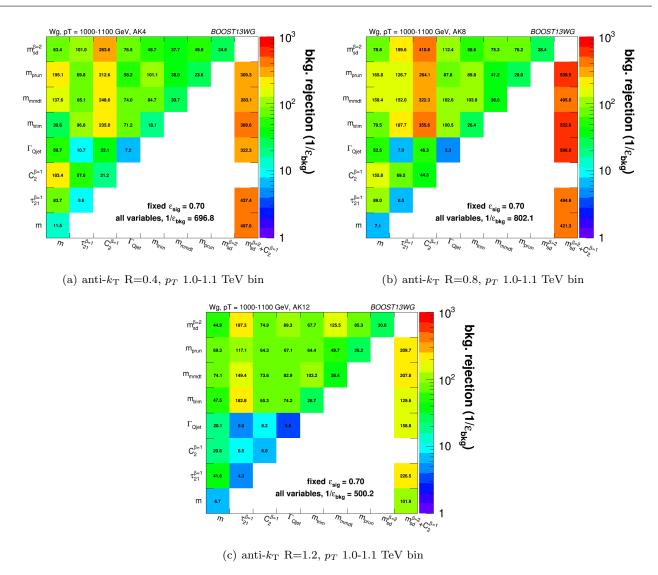

Fig. 15 The background rejection for a fixed signal efficiency (70%) of each BDT combination of each pair of variables considered, in the p_T 1.0-1.1 TeV bin using the anti- k_T R=0.4, R=0.8 and R=1.2 algorithm. Also shown is the background rejection for a BDT combination of all of the variables considered.

lation of the trimmed mass with the ungroomed mass,754 a combination that does not improve on the single mass755 as dramatically, is shown. In all cases one can see that756 there is a much smaller degree of correlation between757 the pruned mass and the ungroomed mass in the back-758 grounds sample than for the trimmed mass and the un-759 groomed mass. This is most obvious in Figure 19, where760 the high degree of correlation between the trimmed and761 ungroomed mass is expected, since with the parameters762 used (in particular $R_{trim} = 0.2$) we cannot expect trim-763 ming to have a significant impact on an R=0.4 jet. The764 reduced correlation with ungroomed mass for pruning765 in the background means that, once we have made the766 requirement that the pruned mass is consistent with a W (i.e. \sim 80 GeV), a relatively large difference be-

tween signal and background in the ungroomed mass still remains, and can be exploited to improve the background rejection further. In other words, many of the background events which pass the pruned mass requirement do so because they are shifted to lower mass (to be within a signal mass window) by the grooming, but these events still have the property that they look very much like background events before the grooming. A single requirement on the groomed mass only does not exploit this. Of course, the impact of pile-up, not considered in this study, could significantly limit the degree to which the ungroomed mass could be used to improve discrimination in this way.

6.3.3 "All Variables" Performance

As well as the background rejection at a fixed 70% sig-784 nal efficiency for two-variable combinations, Figures 13, $\frac{1}{2}$ 4 and 15 also report the background rejection achieved₇₈₆ by a combination of all the variables considered into a₇₈₇ single BDT discriminant. One can see that, in all cases,₇₈₈ the rejection power of this "all variables" BDT is signif-₇₈₉ icantly larger than the best two-variable combination.₇₉₀ This indicates that beyond the best two-variable com-₇₉₁ bination there is still significant complementary infor-₇₉₂ mation available in the remaining variables in order to₇₉₃ improve the discrimination of signal and background.₇₉₄ How much complementary information is available ap-₇₉₅ pears to be p_T dependent. In the lower p_T 300-400 and₇₉₆ 500-600 GeV bins the background rejection of the "all₇₉₇

variables" combination is a factor ~ 1.5 greater than the best two-variable combination, but in the highest p_T bin it is a factor ~ 2.5 greater.

The final column in Figures 13, 14 and 15 allows us to explore the all variables performance a little further. It shows the background rejection for three variable BDT combinations of $m_{sd}^{\beta=2}+C_2^{\beta=1}+X$, where X is the variable on the y-axis. For jets with R=0.4 and R=0.8, the combination $m_{sd}^{\beta=2}+C_2^{\beta=1}$ is the best performant (or very close to the best performant) two-variable combination in every p_T bin considered. For R=1.2 this is not the case, as $C_2^{\beta=1}$ is superceded by $\tau_{21}^{\beta=1}$ in performance, as discussed earlier. Thus, in considering the three-variable combination results it is best to focus on the R=0.4 and R=0.8 cases. Here we see that, for the lower p_T 300-400 and 500-600 GeV bins,

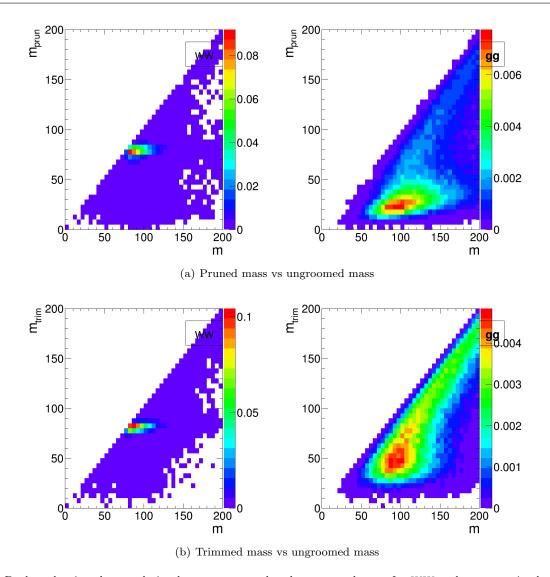

Fig. 20 2-D plots showing the correlation between groomed and ungroomed mass for WW and gg events in the p_T 1.0-1.1 TeV bin using the anti- k_T R=0.8 algorithm.

adding the third variable to the best two-variable com-814 bination brings us to within $\sim 15\%$ of the "all variables" 815 background rejection. However, in the highest p_T 1.0-816 1.1 TeV bin, whilst adding the third variable does im-817 prove the performance considerably, we are still $\sim 40\%$ from the observed "all variables" background rejection, and clearly adding a fourth or maybe even fifth variable would bring considerable gains. In terms of which818 variable offers the best improvement when added to the $m_{sd}^{\beta=2}+C_2^{\beta=1}$ combination, it is hard to see an obvious819 pattern; the best third variable changes depending on820 the p_T and R considered.

In conclusion, it appears that there is a rich and 822 complex structure in terms of the degree to which the 823 discriminatory information provided by the set of vari-824 ables considered overlaps, with the degree of overlaps 825

apparently decreasing at higher p_T . This suggests that in all p_T ranges, but especially at higher p_T , there are substantial performance gains to be made by designing a more complex multivariate W tagger.

6.4 Conclusions

We have studied the performance, in terms of the degree to which a hadronically decaying W boson can be separated from a gluonic background, of a number of groomed jet masses, substructure variables, and BDT combinations of the above. We have used this to build a picture of how the discriminatory information contained in the variables overlaps, and how this comple-

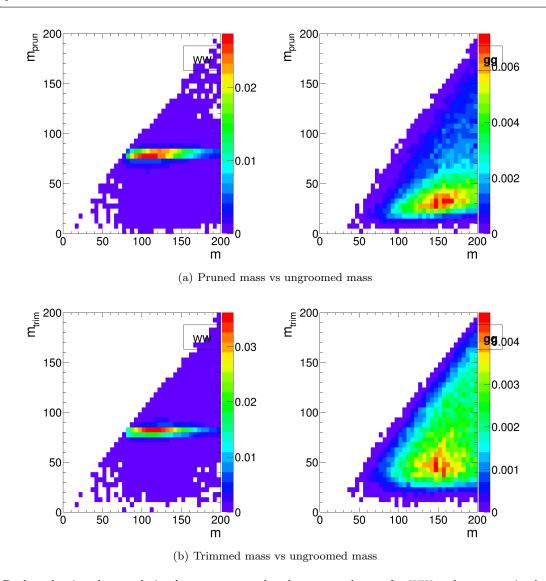

Fig. 21 2-D plots showing the correlation between groomed and ungroomed mass for WW and gg events in the p_T 1.0-1.1 TeV bin using the anti- k_T R=1.2 algorithm.

mentarity between the variables changes with p_T and anti- k_T distance parameter R.

In terms of the performance of individual variables,844 we find that, in agreement with other studies [REF], ins45 general the groomed masses perform best, with a back-846 ground rejection power that increases with increasing847 p_T , but which is more constant with respect to changes848 in R. Conversely, the performance of other substructure849 variables, such as $C_2^{\beta=1}$ and $\tau_{21}^{\beta=1}$ is more susceptible to850 changes in radius, with background rejection power de-851 creasing with increasing R.

The best two-variable performance is obtained by second by a groomed mass with a substructure variable. Which particular substructure variable works be state in combination is strongly dependent on p_T and R. Second by the second by th at smaller R, owing to the small degree of correlation between the variables. However, the sensitivity of $C_2^{\beta=1}$ to soft, wide-angle radiation leads to worse discrimination power at large R, where $\tau_{21}^{\beta=1}$ performs better in combination. Our studies also demonstrate the potential for enhanced discrimination by combining groomed and ungroomed mass information, although the use of ungroomed mass in this may in practice be limited by the presence of pile-up that is not considered in these studies.

By examining the performance of a BDT combination of all the variables considered, it is clear that there are potentially substantial performance gains to be made by designing a more complex multivariate W tagger, especially at higher p_T .

7 Top Tagging

In this section, we study the identification of boosted₉₀₈ top quarks at Run II of the LHC. Boosted top quarks₉₀₉ result in large-radius jets with complex substructure,₉₁₀ containing a b-subjet and a boosted W. The additional₉₁₁ kinematic handles coming from the reconstruction of₉₁₂ the W mass and b-tagging allows a very high degree,₉₁₃ of discrimination of top quark jets from QCD back-₉₁₄ grounds.

We consider top quarks with moderate boost (600-916 1000 GeV), and perhaps most interestingly, at high₉₁₇ boost ($\gtrsim 1500$ GeV). Top tagging faces several chal-918 lenges in the high- p_T regime. For such high- p_T jets₉₁₉ the b-tagging efficiencies are no longer reliably known-920 Also, the top jet can also accompanied by additional₉₂₁ radiation with $p_T \sim m_t$, leading to combinatoric ambi-922 guities of reconstructing the top and W, and the pos-923 sibility that existing taggers or observables shape the₉₂₄ background by looking for subjet combinations that re-925 construct m_t/m_W . To study this, we examine the per-926 formance of both mass-reconstruction variables, as well₉₂₇ as shape observables that probe the three-pronged na-928 ture of the top jet and the accompanying radiation pat-929 tern.

We use the top quark MC samples described in Sec- $_{931}$ tion 2.2. The analysis relies on FASTJET 3.0.3 for jet clustering and calculation of jet substructure observ- $_{932}$ ables. Jets are clustered using the anti- k_t algorithm. An upper and lower p_T cut are applied after jet clus- $_{934}$ tering to each sample to ensure similar p_T spectra in $_{935}$ each bin. The bins in leading jet p_T that are investigated for top tagging are 600-700 GeV, 1-1.1 TeV, and 1.5-1.6 TeV. Jets are clustered with radii R = 0.4, 0.8, and 1.2; R = 0.4 jets are only studied in the 1.5-1.6 TeV bin because for top quarks with this boost, the $_{939}^{939}$ top decay products are all contained within an R = 0.4

7.1 Methodology

We study a number of top-tagging strategies, in partic-944 ular: 945

- 1. HEPTopTagger
- 2. Johns Hopkins Tagger (JH)
- 3. Trimming
- 4. Pruning

The top taggers have criteria for reconstructing a top₉₅₁ and W candidate, and a corresponding top and W mass₉₅₂ as described in Section 3.3, while the grooming algo-₉₅₃ rithms (trimming and pruning) do not incorporate a₉₅₄ W-identification step. For a level playing field, where₉₅₅

grooming is used we construct a W candidate mass, m_W , from the three leading subjets by taking the mass of the pair of subjets with the smallest invariant mass; in the case that only two subjets are reconstructed, we take the mass of the leading subjet. The top mass, m_t , is the mass of the groomed jet. All of the above taggers and groomers incorporate a step to remove pile-up and other soft radiation.

We also consider the performance of jet shape observables. In particular, we consider the N-subjettiness ratios $\tau_{32}^{\beta=1}$ and $\tau_{21}^{\beta=1}$, energy correlation function ratios $C_3^{\beta=1}$ and $C_2^{\beta=1}$, and the Qjet mass volatility Γ . In addition to the jet shape performance, we combine the jet shapes with the mass-reconstruction methods described above to determine the optimal combined performance.

For determining the performance of multiple variables, we combine the relevant tagger output observables and/or jet shapes into a boosted decision tree (BDT), which determines the optimal cut. Additionally, because each tagger has two input parameters, as described in Section 3.3, we scan over reasonable values of the parameters to determine the optimal value that gives the largest background rejection for each top tagging signal efficiency. This allows a direct comparison of the optimized version of each tagger. The input values scanned for the various algorithms are:

- **HEPTopTagger:** $m \in [30, 100] \text{ GeV}, \ \mu \in [0.5, 1]$ - **JH Tagger:** $\delta_p \in [0.02, 0.15], \ \delta_R \in [0.07, 0.2]$ - **Trimming:** $f_{\text{cut}} \in [0.02, 0.14], \ R_{\text{trim}} \in [0.1, 0.5]$ - **Pruning:** $z_{\text{cut}} \in [0.02, 0.14], \ R_{\text{cut}} \in [0.1, 0.6]$

7.2 Single-observable performance

We start by investigating the behaviour of individual jet substructure observables. Because of the rich, three-pronged structure of the top decay, it is expected that combinations of masses and jet shapes will far outperform single observables in identifying boosted tops. However, a study of the top-tagging performance of single variables facilitates a direct comparison with the W tagging results in Section 6, and also allows a straightforward examination of the performance of each observable for different p_T and jet radius.

Fig. 22 shows the ROC curves for each of the top-tagging observables, with the bare (ungroomed) jet mass also plotted for comparison. The jet shape observables all perform substantially worse than jet mass, unlike W tagging for which several observables are competitive with or perform better than jet mass (see, for example, Fig. 8). To understand why this is the case, consider N-subjettiness. The W is two-pronged and the top is three-pronged; therefore, we expect τ_{21} and τ_{32}

to be the best-performant N-subjettiness ratio, respections tively. However, τ_{21} also contains an implicit cut on theologenominator, τ_1 , which is strongly correlated with jeton mass. Therefore, τ_{21} combines both mass and shape into formation to some extent. By contrast, and as is clearons in Fig.22(a), the best shape for top tagging is τ_{32} , which contains no information on the mass. Therefore, it is unto surprising that the shapes most useful for top tagging are less sensitive to the jet mass, and under-perform relative to the corresponding observables for W tagging.1018

Of the two top tagging algorithms, we can see from of 19 Figure 22 that the Johns Hopkins (JH) tagger out¹⁰²⁰ performs the HEPTopTagger in terms of its signal-to¹⁰²¹ background separation power in both the top and W^{1022} candidate masses. In Figure 23 we show the histogram $\023 for the top mass output from the JH and HEPTopTag¹⁰²⁴ ger for different R in the p_T 1.5-1.6 TeV bin, and in 025 Figure 24 for different p_T at at R =0.8, optimized at 026 a signal efficiency of 30%. One can see from these fig¹⁰²⁷ ures that the likely reason for the better performance of 028 the JH tagger is that, in the HEPTopTagger algorithm, 1029 the jet is filtered to select the five hardest subjets, and 030 then three subjets are chosen which reconstruct the top 031 mass. This requirement tends to shape a peak in the 032 QCD background around m_t for the HEPTopTagger, 1033 while the JH tagger has no such requirement. It has 034 been suggested by Anders et al. [?] that performance the been suggested by Anders et al. in the HEPTopTagger may be improved by selecting the 036 three subjets reconstructing the top only among those 037 that pass the W mass constraints, which somewhat 038 reduces the shaping of the background. The discrep 1039 ancy between the JH and HEPTopTaggers is more pro¹⁰⁴⁰ nounced at higher p_T and larger jet radius (see Figs. 27^{041} and 30). Note that both the JH tagger and the HEP1042 TopTagger are superior to the grooming algorithms at 043 using the W candidate inside of the top for signal dis¹⁰⁴⁴ crimination; this is because the the pruning and trim¹⁰⁴⁵ ming algorithms do not have inherent W-identification 1046 steps and are not optimized for this purpose.

In Figures 25 and 27 we directly compare $\mathrm{ROC}^{0^{48}}$ curves for jet shape observable performance and top mass performance respectively in the three different p_T^{1050} bins considered whilst keeping the jet radius fixed at $\mathrm{R=}0.8$. The input parameters of the taggers, groomers and shape variables are separately optimized in each₀₅₂ p_T bin. One can see from Figure 25 that the tagging performance of jet shapes do not change substantially₀₅₃ with p_T . The observables $\tau_{32}^{(\beta=1)}$ and Qjet volatility Γ_{054} have the most variation and tend to degrade with higherosphic p_T, as can be seen in Figure 26. This makes sense, aso₅₆ higher- p_T QCD jets have more, harder emissions withinosphible jet, giving rise to substructure that fakes the signosphible py contrast, from Figure 27 we can see that most₀₅₉

of the top mass observables have superior performance at higher p_T due to the radiation from the top quark becoming more collimated. The notable exception is the HEPTopTagger, which degrades at higher p_T , likely in part due to the background-shaping effects discussed earlier.

In Figures 28 and 30 we directly compare ROC curves for jet shape observable performance and top mass performance respectively for the three different jet radii considered within the p_T 1.5-1.6 TeV bin. Again, the input parameters of the taggers, groomers and shape variables are separately optimized for each jet radius. We can see from these figures that most of the top tagging variables, both shape and reconstructed top mass, perform best for smaller radius. This is likely because, at such high p_T , most of the radiation from the top quark is confined within R = 0.4, and having a larger jet radius makes the observable more susceptible to contamination from the underlying event and other uncorrelated radiation. In Figure 29, we compare the individual top signal and QCD background distributions for each shape variable considered in the p_T 1.5-1.6 TeV bin for the various jet radii. One can see that the distributions for both signal and background broaden with increasing R, degrading the discriminating power. For $C_2^{(\beta=1)}$ and $C_3^{(\beta=1)}$, the background distributions are shifted upward as well. Therefore, the discriminating power generally gets worse with increasing R. The main exception is for $C_3^{(\beta=1)}$, which performs optimally at R = 0.8; in this case, the signal and background coincidentally happen to have the same distribution around R = 0.4, and so R = 0.8 gives better discrimination. ED: Should we also include 1-D plots comparing signal vs bkgd in the top mass, and how this varies with radius? Having said that, there a a lot of 1-D plots here already, might want to try and cut down. (How about now? I've added them to Fig. 26, 27, and removed some other plots. We should decide if we want them; if we do, we need to explain about how the optimization at $\epsilon_S = 0.3 - 0.35$ prefers an aggressive trimmer which suppresses the background mass but also tends to give a spurious peak around m_W .

7.3 Performance of multivariable combinations

We now consider various BDT combinations of the observables from Section 7.2, using the techniques described in Section 4. In particular, we consider the performance of individual taggers such as the JH tagger and HEPTopTagger, which output information about the top and W candidate masses and the helicity angle; groomers, such as trimming and pruning, which

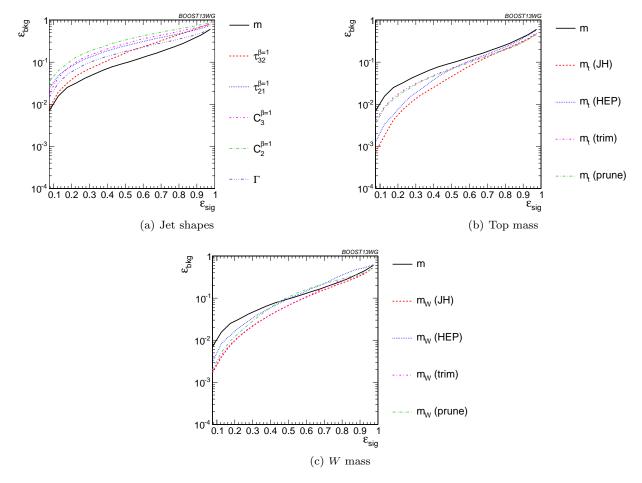

Fig. 22 Comparison of single-variable top-tagging performance in the $p_T = 1-1.1$ GeV bin using the anti- k_T , R=0.8 algorithm.

remove soft, uncorrelated radiation from the top can₇₀₈₁ didate to improve mass reconstruction, and to which₁₀₈₂ we have added a W reconstruction step; and the com₇₀₈₃ bination of the outputs of the above taggers/groomers₄₀₈₄ both with each other, and with shape variables such as₅₀₈₅ N-subjettiness ratios and energy correlation ratios. For₅₀₈₆ all observables with tuneable input parameters, we scan₅₀₈₇ and optimize over realistic values of such parameters₄₀₈₈ as described in Section 7.1.

 complementary information in the mass outputs from different top taggers, we also consider in Figure 31 a multivariable combination of all of the JH and HEP-TopTagger outputs. The maximum efficiency of the combined JH and HEPTopTaggers is limited, as some fraction of signal events inevitably fails either one or other of the taggers. We do see a 20-50% improvement in performance when combining all outputs, which suggests that the different algorithms used to identify the top and W for different taggers contains complementary information.

In Figure 32 we present the results for multivariable combinations of the top tagger outputs with and without shape variables. We see that, for both the HEP-TopTagger and the JH tagger, the shape observables contain additional information uncorrelated with the masses and helicity angle, and give on average a factor 2-3 improvement in signal discrimination. We see that, when combined with the tagger outputs, both the energy correlation functions $C_2 + C_3$ and the N-subjettiness ratios $\tau_{21} + \tau_{32}$ give comparable perfor-

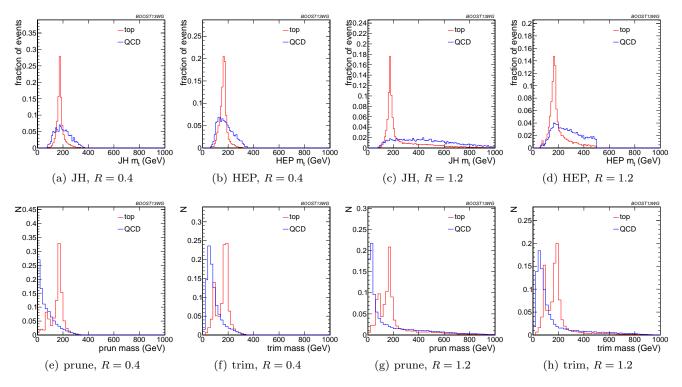

Fig. 23 Comparison of top mass reconstruction with the Johns Hopkins (JH), HEPTopTaggers (HEP), pruning, and trimming at different R using the anti- $k_{\rm T}$ algorithm, $p_{\rm T}=1.5-1.6$ TeV. Each histogram is shown for the working point optimized for best performance with m_t in the 0.3-0.35 signal efficiency bin, and is normalized to the fraction of events passing the tagger. In this and subsequent plots, the HEPTopTagger distribution cuts off at 500 GeV because the tagger fails to tag jets with a larger mass.

mance, while the Qiet mass volatility is slightly worse;126 this is unsurprising, as Qjets accesses shape informa_{±127} tion in a more indirect way from other shape observ₊₁₂₈ ables. Combining all shape observables with a single top₁₂₉ tagger provides even greater enhancement in discrimi+130 nation power. We directly compare the performance of 131 the JH and HEPTopTaggers in Figure 32(c). Combin+132 ing the taggers with shape information nearly erases₁₃₃ the difference between the tagging methods observed in $_{134}$ Figure 31; this indicates that combining the shape $in_{\overline{1}_{135}}$ formation with the HEPT opTagger identifies the differ $_{\overline{1}136}$ ences between signal and background missed by the $tag_{\bar{1}137}$ ger alone. This also suggests that further improvement,138 to discriminating power may be minimal, as various,139 multivariable combinations are converging to within a_{140} factor of 20% or so.

In Figure 33 we present the results for multivari¹¹⁴² able combinations of groomer outputs with and without¹⁴³ shape variables. As with the tagging algorithms, com¹¹⁴⁴ binations of groomers with shape observables improves¹⁴⁵ their discriminating power; combinations with $\tau_{32} + \tau_{21}$ ¹⁴⁶ perform comparably to those with $C_3 + C_2$, and both¹⁴⁷ of these are superior to combinations with the mass¹⁴⁸ volatility, Γ . Substantial improvement is further possi¹⁴⁹

ble by combining the groomers with all shape observables. Not surprisingly, the taggers that lag behind in performance enjoy the largest gain in signal-background discrimination with the addition of shape observables. Once again, in Figure 33(c), we find that the differences between pruning and trimming are erased when combined with shape information.

Finally, in Figure 34, we compare the performance of each of the tagger/groomers when their outputs are combined with all of the shape observables considered. One can see that the discrepancies between the performance of the different taggers/groomers all but vanishes, suggesting perhaps that we are here utilising all available signal-background discrmination information, and that this is the optimal top tagging performance that could be achieved in these conditions.

Up to this point we have just considered the combined multivariable performance in the p_T 1.0-1.1 TeV bin with jet radius R=0.8. We now compare the BDT combinations of tagger outputs, with and without shape variables, at different p_T . The taggers are optimized over all input parameters for each choice of p_T and signal efficiency. As with the single-variable study, we consider anti- k_T jets clustered with R=0.8 and compare

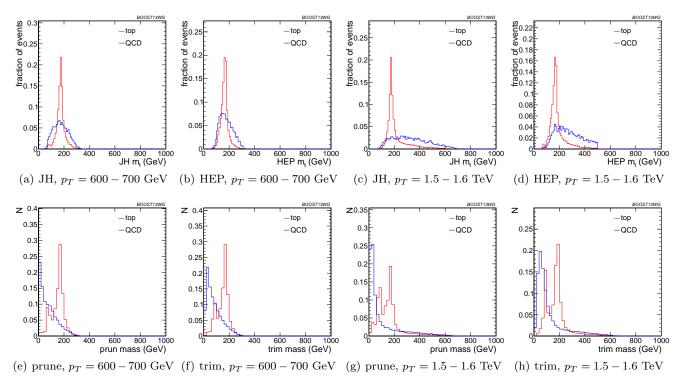

Fig. 24 Comparison of top mass reconstruction with the Johns Hopkins (JH), HEPTopTaggers (HEP), pruning, and trimming at different p_T using the anti- k_T algorithm, R = 0.8. Each histogram is shown for the working point optimized for best performance with m_t in the 0.3 - 0.35 signal efficiency bin, and is normalized to the fraction of events passing the tagger.

the outcomes in the $p_T=500-600~{\rm GeV},\,p_T=1-1.1_{175}~{\rm TeV},\,$ and $p_T=1.5-1.6~{\rm TeV}$ bins. The comparison of the taggers/groomers is shown in Figure 35. The behaviour with p_T is qualitatively similar to the behaviour of the m_t observable for each tagger/groomer shown in Figure 27; this suggests that the p_T behaviour of the taggers is dominated by the top mass reconstruction taggers is dominated by the top mass reconstruction slightly with increased p_T due to the background shapping effect, while the JH tagger and groomers modestly improve in performance.

In Figure 36, we show the p_T dependence of BDT₁₈₇ combinations of the JH tagger output combined with₁₈₈ shape observables. We find that the curves look nearly₁₈₉ identical: the p_T dependence is dominated by the top₁₉₀ mass reconstruction, and combining the tagger outputs₁₉₁ with different shape observables does not substantially₁₉₂ change this behaviour. The same holds true for trim_{T193} ming and pruning. By contrast, HEPTopTagger ROC₁₉₄ curves, shown in Figure 37, do change somewhat when combined with different shape observables; due to the suboptimal performance of the HEPTopTagger at high₁₉₅ p_T , we find that combining the HEPTopTagger with $C_3^{(\beta=1)}$, which in Figure 25(b) is seen to have some mod₁₉₆ est improvement at high p_T , can improve its perfor₁₉₇

mance. Combining the HEPTopTagger with multiple shape observables gives the maximum improvement in performance at high p_T relative to at low p_T .

In Figure 38 we compare the BDT combinations of tagger outputs, with and without shape variables, at different jet radius R in the $p_T = 1.5 - 1.6$ TeV bin. The taggers are optimized over all input parameters for each choice of R and signal efficiency. We find that, for all taggers and groomers, the performance is always best at small R; the choice of R is sufficiently large to admit the full top quark decay at such high p_T , but is small enough to suppress contamination from additional radiation. This is not altered when the taggers are combined with shape observable. For example, in Figure 39 is shown the depedence on R of the JH tagger when combined with shape observables, where one can see that the R-dependence is identical for all combinations. The same holds true for the HEPTopTagger, trimming, and pruning.

7.4 Performance at Sub-Optimal Working Points

Up until now, we have re-optimized our tagger and groomer parameters for each p_T , R, and signal efficiency

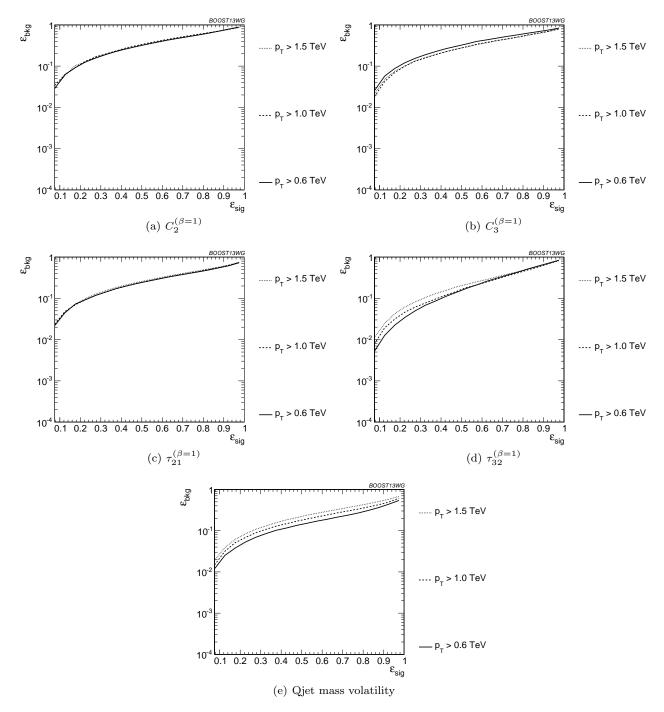

Fig. 25 Comparison of individual jet shape performance at different p_T using the anti- k_T R=0.8 algorithm.

working point. In reality, experiments will choose a fi $_{1206}$ nite set of working points to use. How do our results207 hold up when this is taken into account? To address this208 concern, we replicate our analyses, but only optimize209 the top taggers for a particular p_T/R /efficiency and ap $_{1210}$ ply the same parameters to other scenarios. This allow $_{1213}$ us to determine the extent to which re-optimization is $_{1213}$ necessary to maintain the high signal-background dis $_{1213}$

crimination power seen in the top tagging algorithms we study. The shape observables typically do not have any input parameters to optimize. Therefore, we focus on the taggers and groomers, and their combination with shape observables, in this section.

Optimizing at a single p_T : We show in Figure 40 the performance of the top taggers, using just the reconstructed top mass as the discriminating variable, with

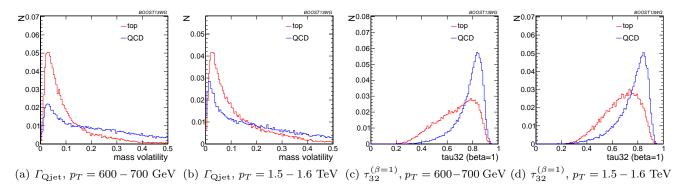

Fig. 26 Comparison of Γ_{Qjet} and $\tau_{32}^{\beta=1}$ at R=0.8 and different values of the p_T . These shape observables are the most sensitive to varying p_T .

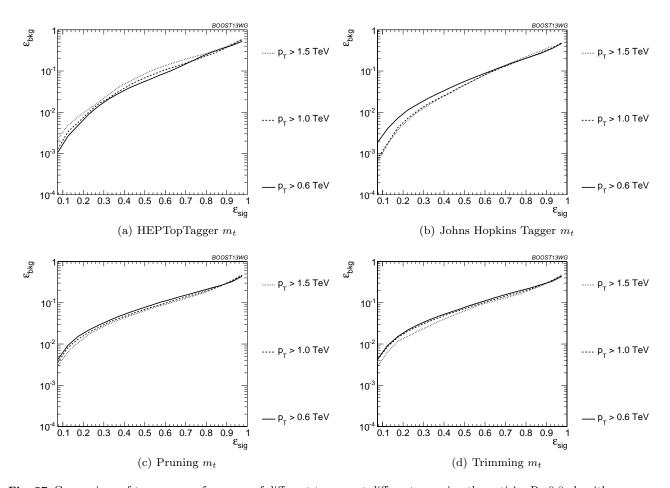

Fig. 27 Comparison of top mass performance of different taggers at different p_T using the anti- k_T R=0.8 algorithm.

all input parameters optimized to the $p_T = 1.5 - 1.6_{221}$ TeV bin, relative to the performance optimized at each₂₂₂ p_T . We see that while the performance degrades by₂₂₃ about 50% when the high- p_T optimized points are used₂₂₄ at other momenta, this is only an order-one adjust₂₂₅ ment of the tagger performance, with trimming and the₂₂₆ Johns Hopkins tagger degrading the most. The jagged₂₂₇

behaviour of the points is due to the finite resolution of the scan. We also observe a particular effect associated with using suboptimal taggers: since taggers sometimes fail to return a top candidate, parameters optimized for a particular efficiency ε_S at $p_T=1.5-1.6$ TeV may not return enough signal candidates to reach the same efficiency at a different p_T . Consequently, no point appears

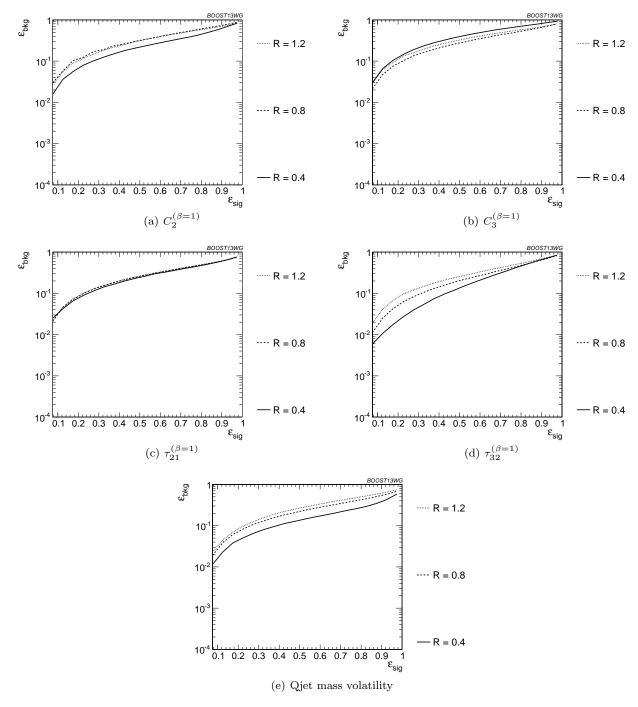

Fig. 28 Comparison of individual jet shape performance at different R in the $p_T = 1.5 - 1.6$ TeV bin.

for that p_T value. This is not often a practical concern,²³⁶ as the largest gains in signal discrimination and signif₁₂₃₇ icance are for smaller values of ε_S , but it is something₂₃₈ that must be considered when selecting benchmark tag₁₂₃₉ ger parameters and signal efficiencies.

The degradation in performance is more pronounced²⁴¹ for the BDT combinations of the full tagger outputs;²⁴² shown in Figure 41), particularly at very low signal effi-

ciency where the optimization picks out a cut on the tail of some distribution that depends precisely on the p_T/R of the jet. Once again, trimming and the Johns Hopkins tagger degrade more markedly. Similar behaviour holds for the BDT combinations of tagger outputs plus all shape observables.

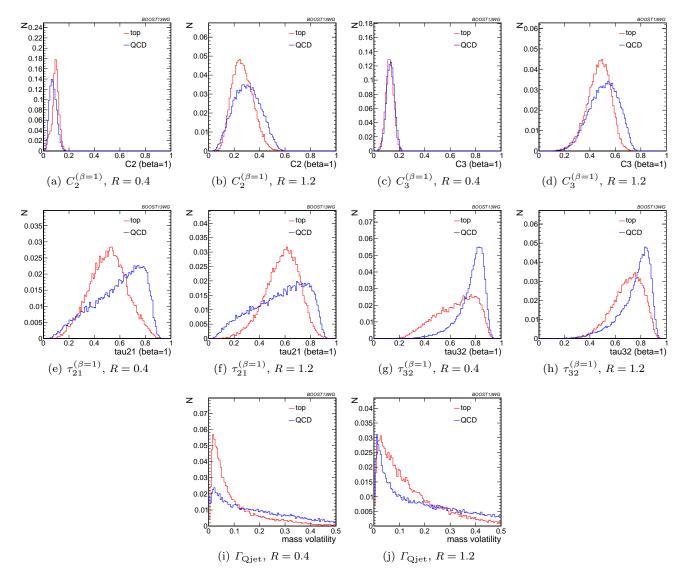

Fig. 29 Comparison of various shape observables in the $p_T = 1.5 - 1.6$ TeV bin and different values of the anti- k_T radius R.

Optimizing at a single R: We perform a similar anal_{t258} ysis, optimizing tagger parameters for each signal ef_{t259} ficiency at R=1.2, and then use the same parame_{t260} ters for smaller R, in the p_T 1.5-1.6 TeV bin. In Fig_{t261} ure 42 we show the ratio of the performance of th \mathfrak{q}_{262} top taggers, using just the reconstructed top mass a \mathfrak{q}_{263} the discriminating variable, with all input parameter \mathfrak{q}_{264} optimized to the R=1.2 values compared to input₂₆₅ parameters optimized separately at each radius. Whil \mathfrak{q}_{266} the performance of each observable degrades at small₂₆₇ $\epsilon_{\rm sig}$ compared to the optimized search, the HEPTop_{t268} Tagger fares the worst as the observed is quite sensitive₂₆₉ to the selected value of R. It is not surprising that \mathfrak{q}_{270} tagger whose top mass reconstruction is susceptible top₂₇₁ background-shaping at large R and p_T would require \mathfrak{q}_{272}

more careful optimization of parameters to obtain the best performance.

The same holds true for the BDT combinations of the full tagger outputs, shown in Figure 43). The performance for the sub-optimal taggers is still within an O(1) factor of the optimized performance, and the HEPTop-Tagger performs better with the combination of all of its outputs relative to the performance with just m_t . The same behaviour holds for the BDT combinations of tagger outputs and shape observables.

Optimizing at a single efficiency: The strongest assumption we have made so far is that the taggers can be reoptimized for each signal efficiency point. This is useful for making a direct comparison of the power of different top tagging algorithms, but is not particularly

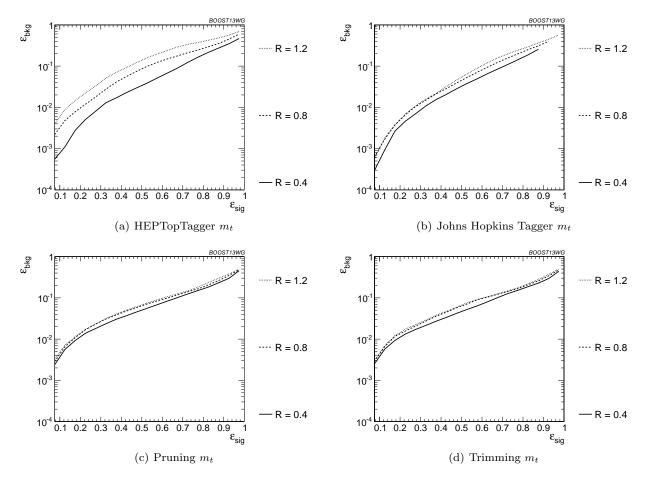

Fig. 30 Comparison of top mass performance of different taggers at different R in the $p_T = 1.5 - 1.6$ TeV bin.

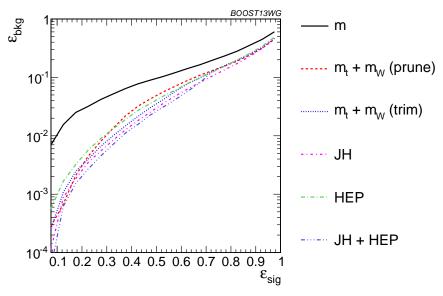

Fig. 31 The performance of the various taggers in the $p_T = 1 - 1.1$ TeV bin using the anti- k_T R=0.8 algorithm. For the groomers a BDT combination of the reconstructed m_t and m_W are used. Also shown is a multivariable combination of all of the JH and HEPTopTagger outputs. The ungroomed mass performance is shown for comparison.

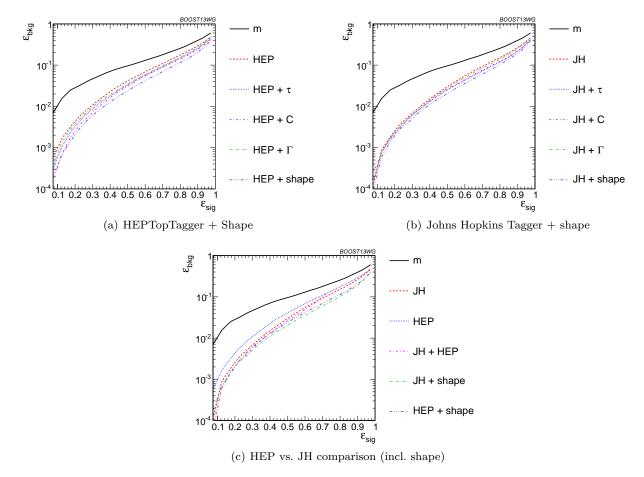

Fig. 32 The performance of BDT combinations of the JH and HepTopTagger outputs with various shape observables in the $p_T=1-1.1$ TeV bin using the anti- k_T R=0.8 algorithm. Taggers are combined with the following shape observables: $\tau_{21}^{(\beta=1)} + \tau_{32}^{(\beta=1)}$, $C_2^{(\beta=1)} + C_3^{(\beta=1)}$, $\Gamma_{\rm Qjet}$, and all of the above (denoted "shape").

practical for the LHC analyses. We now consider the effects when the tagger inputs are optimized once, in the $\varepsilon_S = 0.3-0.35$ bin, and then used to determine the full ROC curve. We do this in the $p_T 1-1.1$ TeV bin and with R=0.8.

The performance of each tagger, normalized to itseed performance optimized in each bin, is shown in Fig1297 ure 44 for cuts on the top mass and W mass, and in298 Figure 45 for BDT combinations of tagger outputs and299 shape variables. In both plots, it is apparent that op1300 timizing the taggers in the 0.3-0.35 efficiency bin gives301 comparable performance over efficiencies ranging from302 0.2-0.5, although performance degrades at small and303 large signal efficiencies. Pruning appears to give espe1304 cially robust signal-background discrimination without305 re-optimization, possibly due to the fact that there are306 no absolute distance or p_T scales that appear in the307 algorithm. Figures 44 and 45 suggest that, while opti1308 mization at all signal efficiencies is a useful tool for com1309

paring different algorithms, it is not crucial to achieve good top-tagging performance in experiments.

7.5 Conclusions

We have studied the performance of various jet substructure observables, groomed masses, and top taggers to study the performance of top tagging at different p_T and jet radius parameter. At each p_T , R, and signal efficiency working point, we optimize the parameters for those observables with tuneable inputs. Overall, we have found that these techniques, individually and in combination, continue to perform well at high p_T , which is important for future LHC running. In general, the John Hopkins tagger performs best, while jet grooming algorithms under-perform relative to the best top taggers due to the lack of an optimized W-identification step. Tagger performance can be improved by a further factor of 2-4 through combination with jet substructure

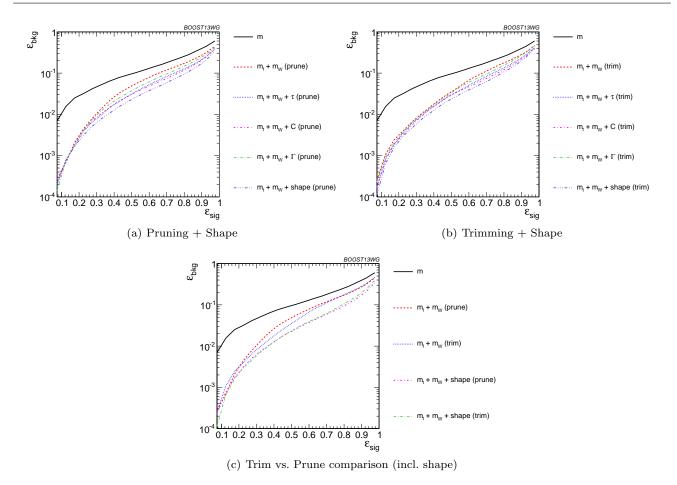

Fig. 33 The performance of the BDT combinations of the trimming and pruning outputs with various shape observables in the $p_T = 1 - 1.1$ TeV bin using the anti- k_T R=0.8 algorithm. Groomer mass outputs are combined with the following shape observables: $\tau_{21}^{(\beta=1)} + \tau_{32}^{(\beta=1)}$, $C_2^{(\beta=1)} + C_3^{(\beta=1)}$, Γ_{Qjet} , and all of the above (denoted "shape").

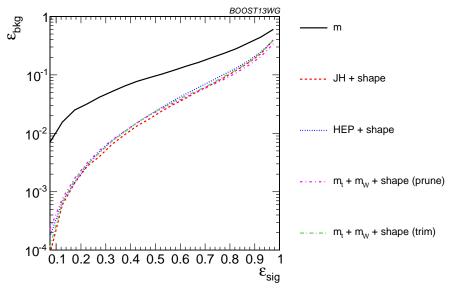

Fig. 34 Comparison of the performance of the BDT combinations of all the groomer/tagger outputs with all the available shape observables in the $p_T=1-1.1$ TeV bin using the anti- k_T R=0.8 algorithm. Tagger/groomer outputs are combined with all of the following shape observables: $\tau_{21}^{(\beta=1)} + \tau_{32}^{(\beta=1)}$, $C_2^{(\beta=1)} + C_3^{(\beta=1)}$, $\Gamma_{\rm Qjet}$.

observables such as τ_{32} , C_3 , and Qjet mass volatility;331 when combined with jet substructure observables, the332 performance of various groomers and taggers becomes333 very comparable, suggesting that, taken together, the334 observables studied are sensitive to nearly all of the335 physical differences between top and QCD jets. A small336 improvement is also found by combining the Johns Hop*337 kins and HEPTopTaggers, indicating that different tag*338 gers are not fully correlated.

Comparing results at different p_T and R, top tag¹³⁴¹ ging performance is generally better at smaller R due³⁴² to less contamination from uncorrelated radiation. Sim¹³⁴³ ilarly, most observables perform better at larger p_T due to the higher degree of collimation of radiation. Some observables fare worse at higher p_T , such as the N-subjettiness ratio τ_{32} and the Qjet mass volatility Γ , as higher- p_T QCD jets have more, harder emissions that fake the top jet substructure. The HEPTopTagger is also worse at large p_T due to the tendency of the tagger to shape backgrounds around the top mass. The p_T -and R-dependence of the multivariable combinations is

dominated by the p_T - and R-dependence of the top mass reconstruction component of the tagger/groomer.

Finally, we consider the performance of various observable combinations under the more realistic assumption that the input parameters are only optimized at a single p_T , R, or signal efficiency, and then the same inputs are used at other working points. Remarkably, the performance of all observables is typically within a factor of 2 of the fully optimized inputs, suggesting that while optimization can lead to substantial gains in performance, the general behaviour found in the fully optimized analyses extends to more general applications of each variable.
