5 1 Introduction

The characteristic feature of collisions at the LHC is a 54 center-of-mass energy, 7 TeV in 2010 and 2011, of 8 TeV 55 in 2012, and near 14 TeV with the start of the second 56 phase of operation in 2015, that is large compared to 57 even the heaviest of the known particles. Thus these 58 particles (and also previously unknown ones) will often 59 be produced at the LHC with substantial boosts. As a 60 12 result, when decaying hadronically, these particles will 61 not be observed as multiple jets in the detector, but 62 14 rather as a single hadronic jet with distinctive internal 63 15 substructure. This realization has led to a new era of 64 16 sophistication in our understanding of both standard 65 17 QCD jets and jets containing the decay of a heavy par-66 ticle, with an array of new jet observables and detection 67 19 techniques introduced and studies. To allow the efficient 68 20 sharing of results from these jet substructure studies a 69 21 series of BOOST Workshops have been held on a yearly 70 basis: SLAC (2009, [?]), Oxford University (2010, [?]), 71 23 Princeton University University (2011, [?]), IFIC Va-72 24 lencia (2012 [?]), University of Arizona (2013 [?]), and, ⁷³ 25 most recently, University College London (2014 [?]). Af-74 26 ter each of these meetings Working Groups have func-75 27 tioned during the following year to generate reports 76 28 highlighting the most interesting new results, includ-77 ing studies of ever maturing details. Previous BOOST 78 30 reports can be found at [?,?,?]. 31

The following report from BOOST 2013 thus views the study and implementation of jet substructure techniques as a fairly mature field. The report attempts to focus on the question of the correlations between the plethora of observables that have been developed and employed, and their dependence on the underlying jet parameters, especially the jet radius R and jet p_T . The report is organized as follows: NEED TO GENERATE AN OUTLINE OF THE REPORT - ESPECIALLY AS I UNDERSTAND IT MYSELF.

2 Monte Carlo Samples and Event Selection

 $_{43}$ 2.1 Quark/gluon and W tagging

32

33

34

35

37

39

Samples were generated at $\sqrt{s} = 8$ TeV for QCD di-⁹³ jets, and for W^+W^- pairs produced in the decay of ⁹⁴ a (pseudo) scalar resonance and decaying hadronically. The QCD events were split into subsamples of gg and $q\bar{q}$ events, allowing for tests of discrimination of hadronic W bosons, quarks, and gluons.

Individual gg and $q\bar{q}$ samples were produced at leading order (LO) using Madgraph5, while W^+W^- samples were generated using the JHU Generator to allow for separation of longitudinal and transverse polarizations. Both were generated using CTEQ6L1 PDFs[REF]. The samples were produced in exclusive p_T bins of width 100 GeV, with the slicing parameter chosen to be the p_T of any final state parton or W at LO. At the parton-level the p_T bins investigated were 300-400 GeV, 500-600 GeV and 1.0-1.1 TeV. Since no matching was performed, a cut on any parton was equivalent. The samples were then all showered through Pythia8 (version 8.176) using the default tune 4C.

The showered events were clustered with FastJet $3.03[\mathbf{REF}]$ using the anti- k_{T} algorithm $[\mathbf{REF}]$ with jet radii of R = 0.4, 0.8, 1.2. In both signal and background, an upper and lower cut on the leading jet p_T is applied after showering/clustering, to ensure similar p_T spectra for signal and background in each p_T bin. The bins in leading jet p_T that are investigated in the W-tagging and q/g tagging studies are 300-400 GeV, 500-600 GeV, 1.0-1.1 TeV. The distribution of the leading jet p_T for the gg and WW samples in the 300-400 GeV parton p_T slice prior to the requirement on the leading jet p_T is shown in Figure 11, for the R=0.8 and R=1.2 anti- k_T jet radii considered in this p_T slice. Figures 12 and 13 show the equivalent leading jet p_T distributions for the jet radii considered in the 500-600 GeV and 1.0 - 1.1 TeV slices respectively.

2.2 Top tagging

Samples were generated at $\sqrt{s}=14$ TeV. Standard Model dijet and top pair samples were produced with Sherpa 2.0.0[REF], with matrix elements of up to two extra partons matched to the shower. The top samples included only hadronic decays and were generated in exclusive p_T bins of width 100 GeV, taking as slicing parameter the maximum of the top/anti-top p_T . The QCD samples were generated with a cut on the leading parton-level jet p_T , where parton-level jets are clustered with the anti- k_t algorithm and jet radii of $R=0.4,\,0.8,\,1.2$. The matching scale is selected to be $Q_{\rm cut}=40,60,80$ GeV for the $p_{T\,\rm min}=600,1000,$ and 1500 GeV bins, respectively.

The analysis again relies on FASTJET 3.0.3 for jet clustering and calculation of jet substructure observables, and an upper and lower p_T cut are applied to each sample to ensure similar p_T spectra in each bin.

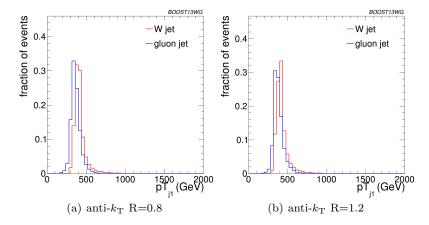

Fig. 1 Comparisons of the leading jet p_T spectrum of the gg background to the WW signal in the p_T 300-400 GeV parton p_T slice using the different anti- k_T jet distance parameters explored in this p_T bin. These distributions are formed prior to the 300-400 GeV leading jet p_T requirement.

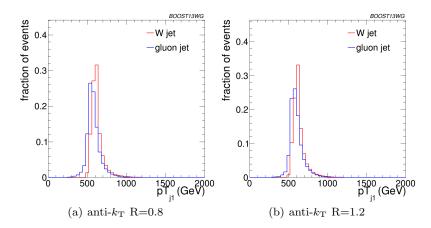

Fig. 2 Comparisons of the leading jet p_T spectrum of the gg background to the WW signal in the p_T 500-600 GeV parton p_T slice using the different anti- k_T jet distance parameters explored in this p_T bin. These distributions are formed prior to the 500-600 GeV leading jet p_T requirement.

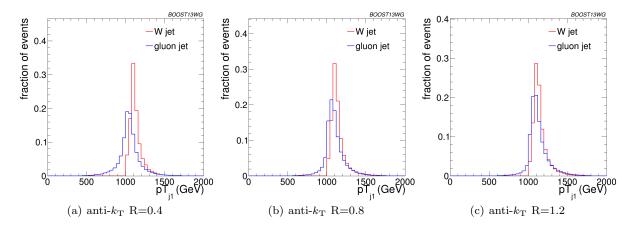

Fig. 3 Comparisons of the leading jet p_T spectrum of the gg background to the WW signal in the p_T 1.0-1.1 TeV parton p_T slice using the different anti- k_T jet distance parameters explored in this p_T bin. These distributions are formed prior to the 500-600 GeV leading jet p_T requirement.

The bins in leading jet p_T that are investigated for top₁₃₄ tagging are 600-700 GeV, 1-1.1 TeV, and 1.5-1.6 TeV_{.135} ED: What jet algorithm is used to define the $p_{T^{136}}$ bins?

3 Jet Algorithms and Substructure Observables

In this section, we define the jet algorithms and observables used in our analysis. Over the course of our study, we considered a larger set of observables, but for the final analysis, we eliminated redundant observables for presentation purposes. In Sections 3.1, 3.2, 3.3 and 3.4 we first describe the various jet algorithms, groomers, taggers and other substructure variables used in these studies, and then in Section 3.5 list which observables are considered in each section of this report, and the exact settings of the parameters used.

3.1 Jet Clustering Algorithms

Jet clustering: Jets were clustered using sequential jet clustering algorithms [REF]. Final state particles $i_{,_{147}}$ j are assigned a mutual distance d_{ij} and a distance to the beam, $d_{i\rm B}$. The particle pair with smallest d_{ij} are recombined and the algorithm repeated until the smallest distance is instead the distance to the beam, $d_{i\rm B}$, in which case i is set aside and labelled as a jet. The distance metrics are defined as

$$d_{ij} = \min(p_{Ti}^{2\gamma}, p_{Tj}^{2\gamma}) \frac{\Delta R_{ij}^2}{R^2}, \tag{1}_{149}^{148}$$

$$d_{i\mathrm{B}} = p_{Ti}^{2\gamma},\tag{2}$$

where $\Delta R_{ij}^2 = (\Delta \eta)^2 + (\Delta \phi)^2$. In this analysis, we use the anti- k_t algorithm $(\gamma = -1)$, the Cambridge/Aachen (C/A) algorithm $(\gamma = 0)[\mathbf{REF}]$, and the k_t algorithm $(\gamma = 1)[\mathbf{REF}]$, each of which has varying sensitivity to soft radiation in defining the jet.

Qjets: We also perform non-deterministic jet clustering[**REF**]. Instead of always clustering the particle pair
with smallest distance d_{ij} , the pair selected for combination is chosen probabilistically according to a measure

$$P_{ij} \propto e^{-\alpha (d_{ij} - d_{\min})/d_{\min}},\tag{3}$$

where $d_{\rm min}$ is the minimum distance for the usual jet clustering algorithm at a particular step. This leads to a different cluster sequence for the jet each time the Qjet₁₆₀ algorithm is used, and consequently different substruc-₁₆₁ ture properties. The parameter α is called the rigidity₁₆₂ and is used to control how sharply peaked the probabil-₁₆₃ ity distribution is around the usual, deterministic value.₁₆₄

The Qjets method uses statistical analysis of the resulting distributions to extract more information from the jet than can be found in the usual cluster sequence. We use $\alpha=0.1$ and 25 trees per event for all the studies presented here.

3.2 Jet Grooming Algorithms

142

Pruning: Given a jet, re-cluster the constituents using the C/A algorithm. At each step, proceed with the merger as usual unless both

$$\frac{\min(p_{Ti}, p_{Tj})}{p_{Tij}} < z_{\text{cut}} \text{ and } \Delta R_{ij} > \frac{2m_j}{p_{Tj}} R_{\text{cut}}, \tag{4}$$

in which case the merger is vetoed and the softer branch discarded. The default parameters used for pruning [REF] in this study are $z_{\rm cut}=0.1$ and $R_{\rm cut}=0.5$. One advantage of pruning is that the thresholds used to veto soft, wide-angle radiation scale with the jet kinematics, and so the algorithm is expected to perform comparably over a wide range of momenta.

Trimming: Given a jet, re-cluster the constituents into subjets of radius R_{trim} with the k_t algorithm. Discard all subjets i with

$$p_{Ti} < f_{\text{cut}} \, p_{TJ}. \tag{5}$$

The default parameters used for trimming [**REF**] in this study are $R_{\text{trim}} = 0.2$ and $f_{\text{cut}} = 0.03$.

Filtering: [REF] Given a jet, re-cluster the constituents into subjets of radius $R_{\rm filt}$ with the C/A algorithm. Redefine the jet to consist of only the hardest N subjets, where N is determined by the final state topology and is typically one more than the number of hard prongs in the resonance decay (to include the leading final-state gluon emission). ED: Do we actually use filtering as described here anywhere?

Soft drop: Given a jet, re-cluster all of the constituents using the C/A algorithm. Iteratively undo the last stage of the C/A clustering from j into subjets j_1 , j_2 . If

$$\frac{\min(p_{T1}, p_{T2})}{p_{T1} + p_{T2}} < z_{\text{cut}} \left(\frac{\Delta R_{12}}{R}\right)^{\beta},$$
 (6)

discard the softer subjet and repeat. Otherwise, take j to be the final soft-drop jet[REF]. Soft drop has two input parameters, the angular exponent β and the soft-drop scale $z_{\rm cut}$, with default value $z_{\rm cut}=0.1$. ED: Soft-drop actually functions as a tagger when $\beta=-1$

3.3 Jet Tagging Algorithms

200

201

202

203

204

206

207

208

209

Modified Mass Drop Tagger: Given a jet, re-cluster₂₁₂ all of the constituents using the C/A algorithm. Itera-₂₁₃ tively undo the last stage of the C/A clustering from j_{214} into subjets j_1 , j_2 with $m_{j_1} > m_{j_2}$. If either

$$m_{j_1} > \mu \, m_j \text{ or } \frac{\min(p_{T1}^2, p_{T2}^2)}{m_j^2} \, \Delta R_{12}^2 < y_{\text{cut}},$$
 (7)²¹⁷

then discard the branch with the smaller transverse²¹⁹ mass $m_T = \sqrt{m_i^2 + p_{Ti}^2}$, and re-define j as the branch²²⁰ with the larger transverse mass. Otherwise, the jet is tagged. If de-clustering continues until only one branch²²² remains, the jet is untagged. In this study we use by default $\mu = 1.0$ and $y_{\text{cut}} = 0.1$.

Johns Hopkins Tagger: Re-cluster the jet using the C/A algorithm. The jet is iteratively de-clustered, and at each step the softer prong is discarded if its p_T is less than $\delta_p p_{\mathrm{T jet}}$. This continues until both prongs are harder than the $p_{\rm T}$ threshold, both prongs are softer than the $p_{\rm T}$ threshold, or if they are too close ($|\Delta \eta_{ij}|$ + $|\Delta\phi_{ij}|<\delta_R$); the jet is rejected if either of the latter conditions apply. If both are harder than the $p_{\rm T}$ threshold, the same procedure is applied to each: this results in 2, 3, or 4 subjets. If there exist 3 or 4 subjets, then the jet is accepted: the top candidate is the sum of the $_{225}$ subjets, and W candidate is the pair of subjets closest₂₂₆ to the W mass. The output of the tagger is m_t , $m_{W_{227}}$ and θ_h , a helicity angle defined as the angle, measured in the rest frame of the W candidate, between the top direction and one of the W decay products.

HEPTopTagger: Re-cluster the jet using the C/A algorithm. The jet is iteratively de-clustered, and at each step the softer prong is discarded if $m_1/m_{12} > \mu$ (there is not a significant mass drop). Otherwise, both prongs are kept. This continues until a prong has a mass $m_i < m$, at which point it is added to the list of subjets. Filter the jet using $R_{\text{filt}} = \min(0.3, \Delta R_{ij})$, keeping the five hardest subjets (where ΔR_{ij} is the distance between the two hardest subjets). Select the three subjets₂₂₈ whose invariant mass is closest to m_t . The output of the₂₂₉ tagger is m_t , m_W , and θ_h , a helicity angle defined as₂₃₀ the angle, measured in the rest frame of the W candi-231 date, between the top direction and one of the W decay₂₃₂ products.

Top Tagging with Pruning: For comparison with 255 the other top taggers, we add a W reconstruction step 256 to the trimming algorithm described above. A W candidate is found as follows: if there are two subjets, the highest-mass subjet is the W candidate (because the

W prongs end up clustered in the same subjet); if there are three subjets, the two subjets with the smallest invariant mass comprise the W candidate. In the case of only one subjet, no W is reconstructed.

Top Tagging with Trimming: For comparison with the other top taggers, we add a W reconstruction step to the trimming algorithm described above. A W candidate is found as follows: if there are two subjets, the highest-mass subjet is the W candidate (because the W prongs end up clustered in the same subjet); if there are three subjets, the two subjets with the smallest invariant mass comprise the W candidate. In the case of only one subjet, no W is reconstructed.

3.4 Other Jet Substructure Observables

Qjet mass volatility: As described above, Qjet algorithms re-cluster the same jet non-deterministically to obtain a collection of interpretations of the jet. For each jet interpretation, the pruned jet mass is computed with the default pruning parameters. The mass volatility, Γ_{Qjet} , is defined as

$$\Gamma_{\text{Qjet}} = \frac{\sqrt{\langle m_J^2 \rangle - \langle m_J \rangle^2}}{\langle m_J \rangle},\tag{8}$$

where averages are computed over the Qjet interpretations.

N-subjettiness: N-subjettiness[**REF**] quantifies how well the radiation in the jet is aligned along N directions. To compute N-subjettiness, $\tau_N^{(\beta)}$, one must first identify N axes within the jet. Then,

$$\tau_N = \frac{1}{d_0} \sum_{i} p_{Ti} \min \left(\Delta R_{1i}^{\beta}, \dots, \Delta R_{Ni}^{\beta} \right), \tag{9}$$

where distances are between particles i in the jet and the axes,

$$d_0 = \sum_i p_{Ti} R^{\beta} \tag{10}$$

and R is the jet clustering radius. The exponent β is a free parameter. There is also some choice in how the axes used to compute N-subjettiness are determined. The optimal configuration of axes is the one that minimizes N-subjettiness; recently, it was shown that the "winner-takes-all" axes can be easily computed and have superior performance compared to other minimization techniques [REF]. ED: Do we use WTA? Otherwise why do we mention this?

A more powerful discriminant is often the ratio,

$$\tau_{N,N-1} \equiv \frac{\tau_N}{\tau_{N-1}}.\tag{11}$$

259

260

261

262

263

264

265

267

268

269

While this is not an infrared-collinear (IRC) safe ob-270 servable, it is calculable [REF] and can be made IRC₂₇₁ safe with a loose lower cut on τ_{N-1} .

Energy correlation functions: The transverse mo-274 mentum version of the energy correlation functions are 275 defined as [REF]:

$$\mathrm{ECF}(N,\beta) = \sum_{i_1 < i_2 < \ldots < i_N \in j} \left(\prod_{a=1}^N p_{Ti_a}\right) \left(\prod_{b=1}^{N-1} \prod_{c=b+1}^N \Delta R_{\mathcal{U}i_c}\right)^{\beta} \mathbf{Multivariate \ Analysis \ Techniques}$$

where i is a particle inside the jet. It is preferable to₂₈₀ work in terms of dimensionless quantities, particularly₂₈₁ the energy correlation function double ratio:

$$C_N^{(\beta)} = \frac{\text{ECF}(N+1,\beta) \, \text{ECF}(N-1,\beta)}{\text{ECF}(N,\beta)^2}.$$
 (13)₂₈₄

This observable measures higher-order radiation from 286 leading-order substructure. 242

3.5 Observables for Each Analysis

Quark/gluon discrimination:

- The ungroomed jet mass, m.
- 1-subjettiness, τ_1^{β} with $\beta = 1, 2$. The N-subjettiness²⁹³ axes are computed using one-pass k_t axis optimiza-
- 1-point energy correlation functions, $C_1^{(\beta)}$ with $\beta = {}^{^{294}}$ 249
- The pruned Qjet mass volatility, Γ_{Qjet} . 251
 - The number of constituents (N_{constits}).

W vs. gluon discrimination:

- The ungroomed, trimmed (m_{trim}) , and pruned (m_{pruph}) jet masses.
- The mass output from the modified mass drop tag- $_{302}$ ger (m_{mmdt}) .
- The soft drop mass with $\beta = -1$, 2 $(m_{\rm sd})$.
- 2-point energy correlation function ratio $C_2^{(\beta=1)}$ (we₃₀₅ also studied $\beta = 2$ but did not show its results be-306 cause it showed poor discrimination power).
- N-subjettiness ratio τ_2/τ_1 with $\beta=1$ and with axes₃₀₈ computed using one-pass k_t axis optimization (we₃₀₉ also studied $\beta = 2$ but did not show its results be-310 cause it showed poor discrimination power).
- The pruned Qjet mass volatility.

Top vs. QCD discrimination:

- The ungroomed jet mass.
- The HEPTopTagger and the Johns Hopkins tagger.313

- Trimming and grooming supplemented with W candidate identification.
- N-subjettiness ratios τ_2/τ_1 and τ_3/τ_2 with $\beta=1$ and the "winner-takes-all" axes.
- 2-point energy correlation function ratios $C_2^{\beta=1}$ and
- The pruned Qjet mass volatility.

Multivariate techniques are used to combine variables into an optimal discriminant. In all cases variables are combined using a boosted decision tree (BDT) as implemented in the TMVA package [?]. We use the BDT implementation including gradient boost. An example of the BDT settings are as follows:

- NTrees=1000
- BoostType=Grad
- Shrinkage=0.1
- UseBaggedGrad=F
- nCuts=10000
- MaxDepth=3

290

291

- UseYesNoLeaf=F
- nEventsMin=200

Exact parameter values are chosen to best reduce the effect of overtraining.

5 Quark-Gluon Discrimination

In this section, we examine the differences between quarkand gluon-initiated jets in terms of substructure variables, and to determine to what extent these variables are correlated. Along the way, we provide some theoretical understanding of these observations. The motivation for these studies comes not only from the desire to "tag" a jet as originating from a quark or gluon, but also to improve our understanding of the quark and gluon components of the QCD background relative to boosted resonances. While recent studies have suggested that quark/gluon tagging efficiencies depend highly on the Monte Carlo generator used, we are more interested in understanding the scaling performance with p_T and R, and the correlations between observables, which are expected to be treated consistently within a single shower scheme. (BS: How about this?)

5.1 Methodology

These studies use the qq and gg samples, described previously in Section 2. Jets are reconstructed using the 314

anti- $k_{\rm T}$ algorithm with radius parameters of 0.4, 0.8 and $_{365}$ 1.2, and have various jet grooming approaches applied, $_{366}$ as described in Section 3.4. Only leading and subleading $_{367}$ jets in each sample are used.

Figure 4 shows a comparison of the p_T and η dis-369 tributions of the quark and gluon samples with $p_T = 370$ 500-600 GeV. The differences in the p_T distributions³⁷¹ can be attributed to different out-of-cone radiation pat-372 terns for quark and gluons (BS: Is this just due to anara increased likelihood of hard ISR/FSR for gg states dues74 to the larger QCD charge?), while the different η distri-375 butions are related to the different parton distribution₃₇₆ functions initiating qq and gg production. The quali-377 tative features of the η distributions do not change as₃₇₈ the R parameter is changed. As the p_T increases, the p_T η distributions peak more strongly near zero, as ex-380 pected. Differences in the p_T distributions between the 381 leading and sub-leading (and quark and gluon-induced)382 jets become smaller as the R parameter is increased, as expected from the physics behind these differences, out-384 lined above.

5.2 Single Variable Discrimination

(BS: Do we want to organize this section similar to^{389} for top tagging, where we first discuss the performance of each observable at fixed R/p_T , and then discuss the variations? It's a little mixed right now.)

Figure 5 shows the mass of jets in the quark and 393 gluon samples when using different groomers, and Fig-394 ure 6 shows similar comparisons for different substruc-395 ture variables. Jets built with the anti- $k_{\rm T}$ algorithm³⁹⁶ with R=0.8 and with $p_T = 500 - 650$ GeV are used.³⁹⁷ Qualitatively, the application of grooming shifts the³⁹⁸ mass distributions towards lower values as expected. No³⁹⁹ clear gain in discrimination can be seen, and for certain⁴⁰⁰ grooming parameters, such as the use of soft drop with⁴⁰¹ $\beta = -1$ a clear loss in discrimination power is observed;⁴⁰² this is because the soft-drop condition for $\beta = -1$ dis-403 cards collinear radiation, and the differences between⁴⁰⁴ quarks and gluons are manifest in the collinear struc-405 ture (spin, splitting functions, etc.). Few variations are 406 observed as the radius parameter of the jet reconstruc-407 tion is increased in the two highest p_T bins. However, 408 for the 300-400 GeV bin, the use of small-R jets pro-409 duces a shift in the mass distributions towards lower₄₁₀ values, so that large-R jet masses are more stable with 411 p_T and small-R jet masses are smaller at low- p_T as ex-412 pected from the spatial constraints imposed by the R_{413} parameter. These statements are explored more quan-414 titatively later in this section.

Among the different substructure variables explored μ_{16} $n_{\rm constits}$ provides the highest separation power, followed μ_{17}

by $C_1^{\beta=0}$ and $C_1^{\beta=1}$ as was also found by the CMS and ATLAS Collaborations [add citations]. The evolution of some of these distributions with p_T and R is less trivial than for the jet masses. In particular, changing the R parameter at high p_T changes significantly the C_a^{β} for $\beta > 0$ and the n_{constits} distributions, while leaving all other distributions qualitatively unchanged. This is illustrated in Figure 7 for $\beta = 0$ and $\beta = 1$ using a = 1in both cases for jets with $p_T = 1 - 1.2$ TeV. The shift towards lower values with changing R is evident for the $C_1^{\beta=1}$ distributions, while the stability of $C_1^{\beta=0}$ can also be observed. These features are present in all p_T bins studied, but are even more pronounced for lower p_T bins. The shape of the Q-jet volatility distribution shows some non-trivial shape that deserves some explanation. Two peaks are observed, one at low volatility values and one at mid-volatility. These peaks are generated by two somewhat distinct populations. The high volatility peak arises from jets that get their mass primarily from soft (and sometimes wide-angle) emissions. The removal of some of the constituents when building Q-jets thus changes the mass significantly, increasing the volatility. The lower volatility peak corresponds to jets for which mass is generated by a hard emission, which makes the fraction of Q-jets that change the mass significantly to be smaller. Since the probability of a hard emission is proportional to the color charge (squared), the volatility peak is higher for gluon jets by about the color factor C_A/C_F .

To more quantitatively study the power of each observable as a discriminator for quark/gluon tagging, Receiver Operating Characteristic (ROC) curves are built by scanning each distribution and plotting the background efficiency (to select gluon jets) vs. the signal efficiency (to select quark jets). Figure 8 shows these ROC curves for all of the variables shown in Figure 6 and the ungroomed mass, representing the best performing mass variable, for jets of $p_T = 300 - 400$ GeV. In addition, the ROC curve for the tagger built from a BDT combining all the variables. The details of how the BDT is constructed are explained in Section 4.

Clearly, $n_{\rm constits}$ is the best performing variable for all Rs, even though $C_1^{\beta=0}$ is close, particularly for R=0.8. Most other variables have similar performance, except the Q-jet volatility, which shows significantly worse discrimination (this may be due to our choice of rigidity $\alpha=0.1$, while other studies suggest that a smaller value, such as $\alpha=0.01$, produces better results). The combination of all variables shows somewhat better discrimination. The overall discriminating power decreases with increasing R (BS: Do we understand if this is due to increased contamination from UE, or if this is an actual physical effect?), and the features discussed for this

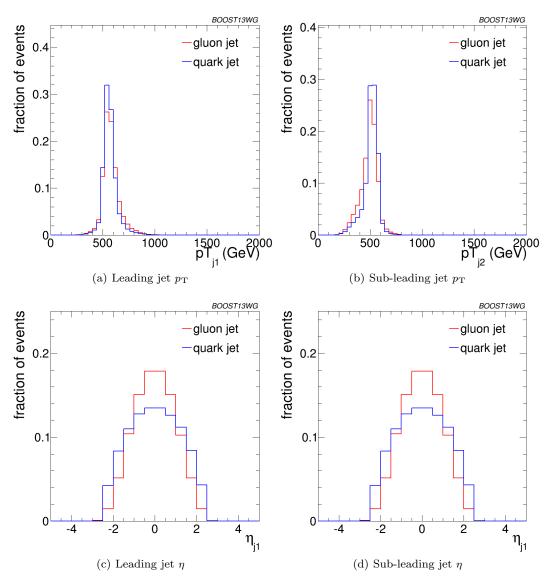

Fig. 4 Comparisons of quark and gluon p_T and η distributions in the sample used for the jets of $p_T = 500 - 600$ GeV bin using the anti- k_T R=0.8 algorithm.

433

 p_T bin also apply to the higher p_T bins. This statement is quantified in the next section.

5.3 Correlations and Combined Performance

The combined performance displayed in Fig. 8 is not435 much better than that of single variables. However, that436 improvement in performance can be critical for certain437 analyses requiring a quark/gluon tagger, and poten-438 tially larger in data than in Monte Carlo simulation.439 Furthermore, insight can be gained into the features al-440 lowing for quark/gluon discrimination if how that im-441 provement arises is understood. It is therefore worth442 investigating quantitatively the improvements in per-443

formance: to do so, quark/gluon taggers are built from every pair-wise combination of variables studied in the previous section, as well as the full set of variables using a boosted decision tree.

In order to quantitatively study the value of each variable for quark/gluon tagging, the gluon rejection, defined as $1/\epsilon_{\rm gluon}$, is studied at a fixed quark selection efficiency of 50%. Figure 9 shows the rejection for each individual variable (along the diagonal of the plots) and for each pair-wise combination. The rejection for the BDT combining all variables is also shown on the bottom right of each plot. Results are shown for jets with $p_T=1-1.2$ TeV and for different R parameters. As already observed in the previous section, $n_{\rm constits}$ is the

Boosted objects at the LHC

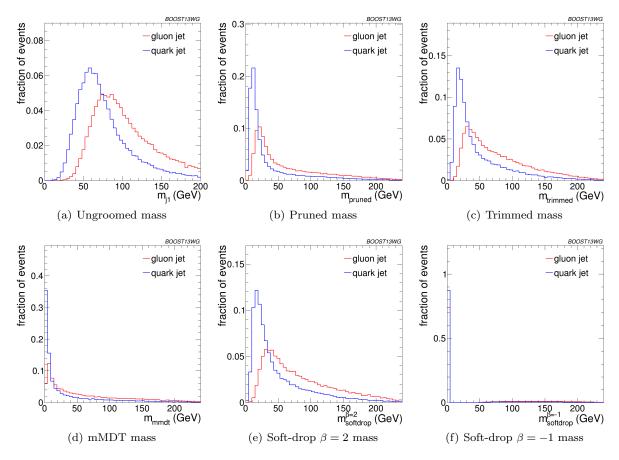

Fig. 5 Comparisons of ungroomed and groomed quark and gluon mass distributions for leading jets in the $p_T = 500 - 650$ GeV bin using the anti- $k_{\rm T}$ R=0.8 algorithm.

most powerful single variable and $C_1^{(\beta=0)}$ follows closely.465 The combination of the two variables is also one of thex66 most powerful combinations for the two large-R collections. Performance is generally better at small R, and 167 in this case other pair-wise combinations are more powerful. In particular, the combinations of $\tau_1^{\beta=1}$ or $C_1^{(\beta=1)_{469}}$ with n_{constits} are capable of getting very close to the 171 rejection achievable through the use of all variables.

The overall loss in performance with increasing R_{474} can be observed in all single variables studied, except₄₇₅ for $C_1^{(\beta=0)}$ and the Q-jet volatility, which are quite re-₄₇₆ silient to increasing R. This is expected, since their dis-₄₇₇ tributions were observed to be also quite insensitive to-₄₇₈ R in the previous section. Their combination, however, does lose performance significantly as R is increased.₄₇₉ [do we understand this?] Of all the variables stud-₄₈₀ ied, $\beta=2$ 1-subjettiness and energy correlation vari-₄₈₁ ables are particularly sensitive to increasing R. This is-₄₈₂ understandable, because for $\beta=2$ a larger weight is-₄₈₃ put in large-angle emissions. However, from other vari-₄₈₄ ables, it is understood that most of the discrimination-₄₈₅

power comes from analyzing a small-R jet, or the center of the large-R jet.

These observations are qualitatively similar across all ranges of p_T . Quantitatively, however, there is a loss of rejection power for the taggers made of a combination of variables as the p_T decreases. This can be observed in Fig. 10 for anti- k_T R=0.4 jets of different p_T s. Clearly, most single variables retain their gluon rejection potential at lower p_T s. However, when combined with other variables, the highest performing pairwise combinations lose ground with respect to other pairwise combinations. This is also reflected in the rejection of the tagger that uses a combination of all variables, which is lower at lower p_T s. [do we understand this?]

(BS: Do we want to explicitly mention some aspects of the correlation, namely quantifying which observables seem to be most correlated and that it seems that the all-variable performance is not much better than some of the pair-wise combinations, and so there seem to be ~ 2 independent observables? Also, I remember Nhan had some tables that showed some variable rankings in

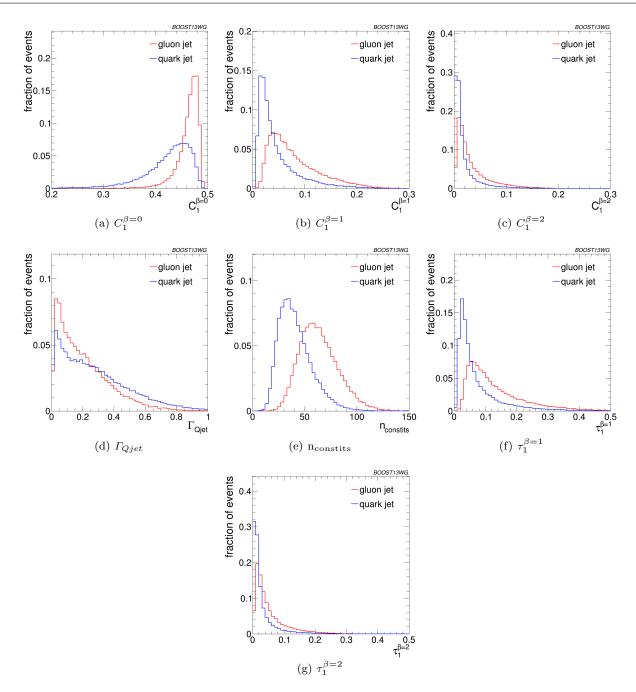

Fig. 6 Comparisons of quark and gluon distributions of different substructure variables for leading jets in the $p_T = 500 - 650$ GeV bin using the anti- k_T R=0.8 algorithm.

terms of how (un)correlated they were; not sure if we

want to show these.

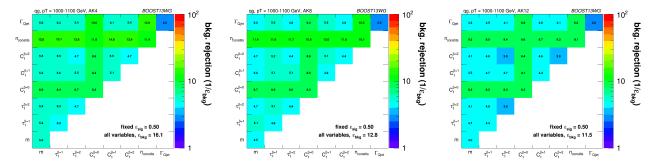

Fig. 9 Gluon rejection defined as $1/\epsilon_{\rm gluon}$ when using each 2-variable combination as a tagger with 50% acceptance for quark jets. Results are shown for jets with $p_T=1-1.2$ TeV and for different R parameters. The rejection obtained with a tagger that uses all variables is also shown in the plots.

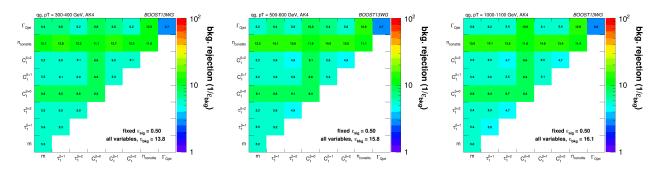

Fig. 10 Gluon rejection defined as $1/\epsilon_{\rm gluon}$ when using each 2-variable combination as a tagger with 50% acceptance for quark jets. Results are shown for R=0.4 jets with $p_T=300-400$ GeV, $p_T=500-600$ GeV and $p_T=1-1.2$ TeV. The rejection obtained with a tagger that uses all variables is also shown in the plots.

88 6 Boosted W-Tagging

algorithm are explored, as well as a variety of kinematic regimes (lead jet p_T 300-400 GeV, 500-600 GeV, 1.0-1.1 TeV). This allows us to determine the performance of observables as a function of jet radius and jet boost, and to see where different approaches may break down. The groomed mass and substructure variables are then combined in a BDT as described in Section 4, and the performance of the resulting BDT discriminant explored through ROC curves to understand the degree to which variables are correlated, and how this changes with jet boost and jet radius.

6.1 Methodology

These studies use the $X \to WW$ samples as signal and the dijet gg samples to model the QCD background, described previously in Section 2. Whilst only gluonic backgrounds are explored here, the conclusions as to the dependence of the performance and correlations on the jet boost and radius have been verified to hold also for gg backgrounds. **ED:** To be checked!

Jets are reconstructed using the anti- $k_{\rm T}$ algorithm, and have various jet grooming approaches applied as described in Section 3.4. The following event selection is then applied to these samples....(presumably this will vary depending on which kinematic bin is used, as will the actual samples used - maybe summarize in a table).

Figure 11 shows a comparison of the leading jet p_T for the signal and background in the p_T 300-400 GeV bin, for the two different anti- k_T jet algorithm distance parameters explored in this bin (R=0.8 and R=1.2). Figures 12 and 13 show the same for the $p_T=500$ -600 GeV bin and $p_T=1.0$ -1.1 TeV bin respectively, where for the $p_T=1.0$ -1.1 TeV bin the distance parameter R=0.4 is also explored because the W radiation at this boost is typically confined to a cone of this size.

(ED: Do we need to show the p_T spectra? Since we end up cutting in a narrow bin, it hopefully shouldn't make a difference.)

6.2 Single Variable Performance

In this section we will explore the performance of the various groomed jet mass and substructure variables in terms of discriminating signal and background, and how this performance changes depending on the kinematic bin and jet radius considered.

Figure 14 the compares the signal and background in terms of the different groomed masses explored for the anti- $k_{\rm T}$ R=0.8 algorithm in the p_T 500-600 bin. One can clearly see that in terms of separating signal and background the groomed masses will be significantly

In this section, we study the discrimination of a boosted bar hadronically decaying W signal against a gluon back-538 ground, comparing the performance of various groomed jet masses, substructure variables, and BDT combina-540 tions of groomed mass and substructure. We produce 180°C curves that elucidate the performance of the vari-542 ous groomed mass and substructure variables. A range 543 of different distance parameters R for the anti- $k_{\rm T}$ jet 544

more performant than the ungroomed anti- $k_{\rm T}$ R=0.8597 mass. Figure 15 compares signal and background in the mass. different substructure variables explored for the sames99 jet radius and kinematic bin.

Figures 16, 17 and 18 show the single variable ROC⁶⁰¹ curves compared to the ROC curve for a BDT combi- $^{602}\,$ nation of all the variables (labelled "allvars"), for each⁶⁰³ of the anti- $k_{\rm T}$ distance parameters considered in each⁶⁰⁴ of the kinematic bins. One can see that, in all cases, 605 the "all vars" option is considerably better $\operatorname{performant}^{606}$ than any of the individual single variables considered, 607 indicating that there is considerable complementarity⁶⁰⁸ between the variables, and this will be explored further 609 in the next section.

Although the ROC curves give all the relevant information, it is hard to compare performance quantitatively. In Figures 19, 20 and 21 are shown matrices $_{614}^{\circ}$ which give the background rejection for a signal effi- $_{\scriptscriptstyle{615}}$ ciency of 70% when two variables (that on the x-axis $_{616}$ and that on the y-axis) are combined in a BDT. These $_{617}$ are shown separately for each p_T bin and jet radius considered. The diagonal of these plots correspond to the background rejections for a single variable BDT,618 and can thus be examined to get a quantitative measure of the individual single variable performance, and 619 to study how this changes with jet radius and momenta.⁶²⁰

One can see that in general the most performant $_{622}^{\circ}$ single variables are the groomed masses. However, in certain kinematic bins and for certain jet radii, $C_2^{\beta=1}$ has a background rejection that is comparable to or $_{\scriptscriptstyle 625}$ better than the groomed masses.

By comparing Figures 19(a), 20(a) and 21(b), web27 can see how the background rejection performance evolves as we increase momenta whilst keeping the jet radius₆₂₉ fixed to R=0.8. Similarly, by comparing Figures 19(b), 29(b) non-mass substructure variable $(C_2^{\beta=1}, \Gamma_{Qjet} \text{ or } \tau_{21}^{\beta=1})$. and 21(c) we can see how performance evolves with $p_{T^{631}}$ for R=1.2. For both R=0.8 and R=1.2 the background632 rejection power of the groomed masses increases with 633 increasing p_T , with a factor 1.5-2.5 increase in rejec-634 tion in going from the 300-400 GeV to 1.0-1.1 TeV bins.635 ED: Add some of the 1-D plots comparing sig-636 nal and bkgd in the different masses and pT bins₆₃₇ here? However, the $C_2^{\beta=1}$, Γ_{Qjet} and $\tau_{21}^{\beta=1}$ substructure₅₃₈ variables behave somewhat differently. The background₆₃₉ rejection power of the Γ_{Qjet} and $\tau_{21}^{\beta=1}$ variables both₆₄₀ decrease with increasing p_T , by up to a factor two-41 in going from the 300-400 GeV to 1.0-1.1 TeV bins.642Conversely the rejection power of $C_2^{\beta=1}$ dramatically₆₄₃ increases with increasing p_T for R=0.8, but does not₆₄₄ improve with p_T for the larger jet radius R=1.2. **ED:**₆₄₅ Can we explain this? Again, should we add some of the 1-D plots?

By comparing the individual sub-figures of Figures 19, 20 and 21 we can see how the background rejection performance depends on jet radius within the same p_T bin. To within $\sim 25\%$, the background rejection power of the groomed masses remains constant with respect to the jet radius. However, we again see rather different behaviour for the substructure variables. In all p_T bins considered the most performant substructure variable, $C_2^{\beta=1}$, performs best for an anti- $k_{\rm T}$ distance parameter of R=0.8. The performance of this variable is dramatically worse for the larger jet radius of R=1.2 (a factor seven worse background rejection in the 1.0-1.1 TeV bin), and substantially worse for R=0.4. For the other jet substructure variables considered, Γ_{Qjet} and $\tau_{21}^{\beta=1}$, their background rejection power also reduces for larger jet radius, but not to the same extent. ED: Insert some nice discussion/explanation of why jet substructure power generally gets worse as we go to large jet radius, but groomed mass performance does not. Probably need the 1-D figures for this.

6.3 Combined Performance

The off-diagonal entries in Figures 19, 20 and 21 can be used to compare the performance of different BDT two-variable combinations, and see how this varies as a function of p_T and R. By comparing the background rejection achieved for the two-variable combinations to the background rejection of the "all variables" BDT, one can understand how much more discrimination is possible by adding further variables to the two-variable BDTs.

One can see that in general the most powerful twovariable combinations involve a groomed mass and a Two-variable combinations of the substructure variables are not powerful in comparison. Which particular mass + substructure variable combination is the most powerful depends strongly on the p_T and R of the jet, as discussed in the sections that follow.

There is also modest improvement in the background rejection when different groomed masses are combined, compared to the single variable groomed mass performance, indicating that there is complementary information between the different groomed masses. In addition, there is an improvement in the background rejection when the groomed masses are combined with the ungroomed mass, indicating that grooming removes some useful discriminatory information from the jet. These observations are explored further in the section below.

Generally one can see that the R=0.8 jets offer the best two-variable combined performance in all p_T bins

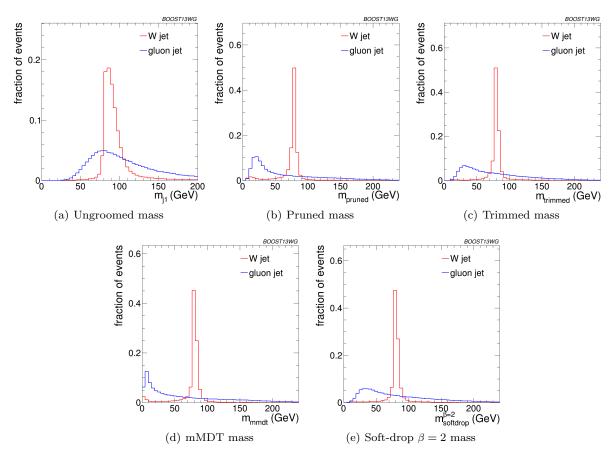

Fig. 14 Comparisons of the QCD background to the WW signal in the p_T 500-600 GeV bin using the anti- k_T R=0.8 algorithm: leading jet mass distributions.

explored here. This is despite the fact that in the high- $_{668}$ est 1.0-1.1 GeV p_T bin the average separation of the $_{69}$ quarks from the W decay is much smaller than 0.8,670 and well within 0.4. This conclusion could of course be $_{71}$ susceptible to pile-up, which is not considered in this $_{673}$ study.

667

As already noted, the largest background rejection at 570% signal efficiency are in general achieved using those 578 two variable BDT combinations which involve a groomed 599 mass and a non-mass substructure variable. For both 590 R=0.8 and R=1.2 jets, the rejection power of these two 591 variable combinations increases substantially with in-592 creasing 594 pere.

For a jet radius of R=0.8, across the full p_T rangess considered, the groomed mass + substructure variabless combinations with the largest background rejection aress those which involve $C_2^{\beta=1}$. For example, in combinations with $m_{sd}^{\beta=2}$, this produces a five-, eight- and fifteen-foldss

increase in background rejection compared to using the groomed mass alone. In Figure 22 the low degree of correlation between $m_{sd}^{\beta=2}$ versus $C_2^{\beta=1}$ that leads to these large improvements in background rejection can be seen. One can also see that what little correlation exists is rather non-linear in nature, changing from a negative to a positive correlation as a function of the groomed mass, something which helps to improve the background rejection in the region of the W mass peak.

However, when we switch to a jet radius of R=1.2 the picture for $C_2^{\beta=1}$ combinations changes dramatically. These become significantly less powerful, and the most powerful variable in groomed mass combinations becomes $\tau_{21}^{\beta=1}$ for all jet p_T considered. Figure 23 shows the correlation between $m_{sd}^{\beta=2}$ and $C_2^{\beta=1}$ in the p_T 1.0 - 1.2 TeV bin for the various jet radii considered. Figure 24 is the equivalent set of distributions for $m_{sd}^{\beta=2}$ and $\tau_{21}^{\beta=1}$. One can see from Figure 23 that, due to the sensitivity of the observable to to soft, wide-angle radiation, as the jet radius increases $C_2^{\beta=1}$ increases and becomes more and more smeared out for both signal and background, leading to worse discrimination power.

Also shown is the background rejection for a BDT combination of all of the variables considered.

704

This does not happen to the same extent for $\tau_{21}^{\beta=1}$. Web97 can see from Figure 24 that the negative correlation between $m_{sd}^{\beta=2}$ and $\tau_{21}^{\beta=1}$ that is clearly visible for R=0.4698 decreases for larger jet radius, such that the groomed699 mass and substructure variable are far less correlated700 and $\tau_{21}^{\beta=1}$ offers improved discrimination within a $m_{sd}^{\beta=2}$ 701 mass window.

6.3.2 Mass + Mass Performance

The different groomed masses and the ungroomed mass are of course not fully correlated, and thus one can always see some kind of improvement in the background rejection (relative to the single mass performance) when two different mass variables are combined in the BDT. However, in some cases the improvement can be dramatic, particularly at higher p_T , and particularly for combinations with the ungroomed mass. For example, in Figure 21 we can see that in the p_T 1.0-1.1 TeV bin

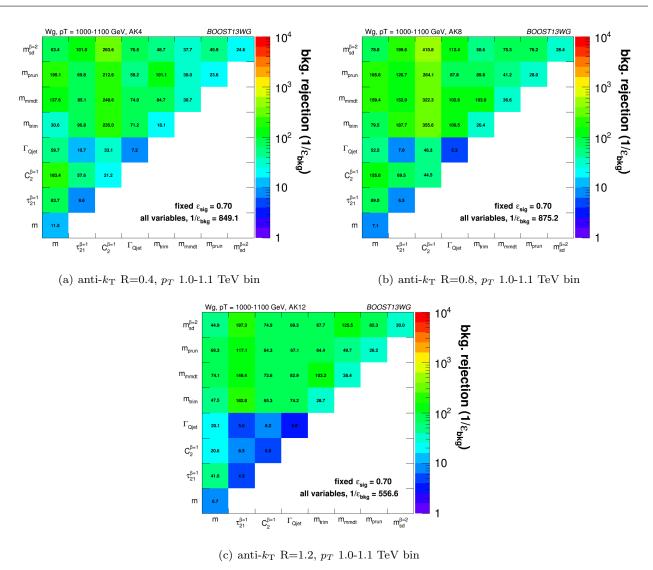

Fig. 21 The background rejection for a fixed signal efficiency (70%) of each BDT combination of each pair of variables considered, in the p_T 1.0-1.1 TeV bin using the anti- k_T R=0.4, R=0.8 and R=1.2 algorithm. Also shown is the background rejection for a BDT combination of all of the variables considered.

the combination of pruned mass with ungroomed mass₇₂₂ produces a greater than eight-fold improvement in the₇₂₃ background rejection for R=0.4 jets, a greater than five-₇₂₄ fold improvement for R=0.8 jets, and a factor \sim two im-₇₂₅ provement for R=1.2 jets. A similar behaviour can be₇₂₆ seen for mMDT mass. In Figures 25, 26 and 27 is shown₇₂₇ the 2-D correlation plots of the pruned mass versus the₇₂₈ ungroomed mass separately for the WW signal and gg_{729} background samples in the p_T 1.0-1.1 TeV bin, for the₇₃₀ various jet radii considered. For comparison, the corre-₇₃₁ lation of the trimmed mass with the ungroomed mass₇₃₂ a combination that does not improve on the single mass₇₃₃ as dramatically, is shown. In all cases one can see that₇₃₄ there is a much smaller degree of correlation between₇₃₅ the pruned mass and the ungroomed mass in the back-₇₃₆

grounds sample than for the trimmed mass and the ungroomed mass. This is most obvious in Figure 25, where the high degree of correlation between the trimmed and ungroomed mass is expected, since with the parameters used (in particular $R_{trim}=0.2$) we cannot expect trimming to have a significant impact on an R=0.4 jet. The reduced correlation with ungroomed mass for pruning in the background means that, once we have made the requirement that the pruned mass is consistent with a W (i.e. ~ 80 GeV), a relatively large difference between signal and background in the ungroomed mass still remains, and can be exploited to improve the background rejection further. In other words, many of the background events which pass the pruned mass requirement do so because they are shifted to lower mass (to

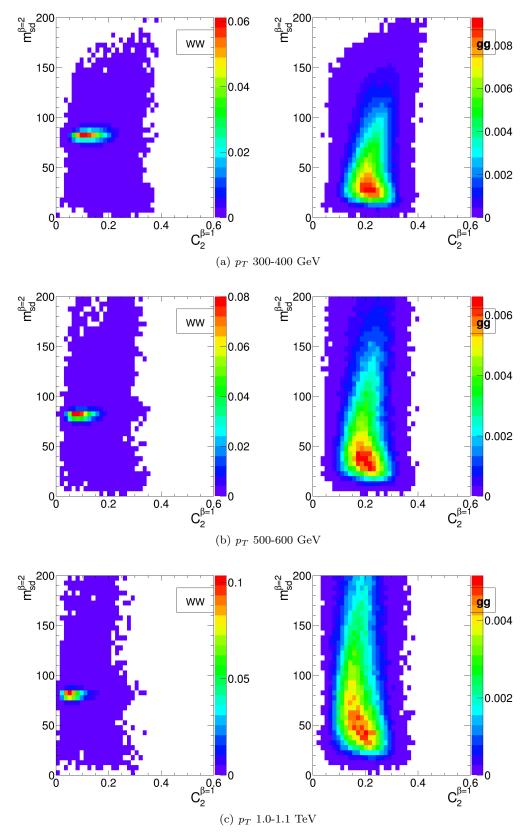

Fig. 22 2-D plots showing $m_{sd}^{\beta=2}$ versus $C_2^{\beta=1}$ for R=0.8 jets in the various p_T bins considered.

be within a signal mass window) by the grooming, but these events still have the property that they look very much like background events before the grooming. A single requirement on the groomed mass only does not exploit this. Of course, the impact of pile-up, not considered in this study, could significantly limit the degree to which the ungroomed mass could be used to improve discrimination in this way.

6.3.3 "All Variables" Performance

As well as the background rejection at a fixed 70% signal efficiency for two-variable combinations, Figures 19, 20 and 21 also report the background rejection achieved by a combination of all the variables considered into a single BDT discriminant. One can see that, in all cases, the rejection power of this "all variables" BDT is significantly larger than the best two-variable combination, by between a factor 2-3. This indicates that beyond the best two-variable combination there is still significant complementary information available in the remaining variables in order to improve the discrimination of signal and background.

ED: This section will be filled in when we have got the 3-variable combination studies, so we have a better idea where the dramatic increase in rejection power with "all variables" is coming from. Would also be good to show perhaps some of the "all variables" BDT discriminants in 1-D plots.

7 Top Tagging

radiation with $p_T \sim m_t$, leading to combinatoric ambiguities of reconstructing the top and W, and the possibility that existing taggers or observables shape the background by looking for subjet combinations that reconstruct m_t/m_W . To study this, we examine the performance of both mass-reconstruction variables, as well as shape observables that probe the three-pronged nature of the top jet and the accompanying radiation pattern.

7.1 Methodology

We study a number of top-tagging strategies, in particular:

- 1. HEPTopTagger
- 2. Johns Hopkins Tagger (JH)
- 3. Trimming
- 4. Pruning

In this section, we study the identification of boosted top quarks at Run II of the LHC. Boosted top quarks result in large-radius jets with complex substructure, containing a b-subjet and a boosted W. The additional kinematic handles coming from the reconstruction of the W mass and b-tagging allows a very high degree of discrimination of top quark jets from QCD back-grounds.

The top taggers have criteria for reconstructing a top and W candidate, while the grooming algorithms (trimming and pruning) do not incorporate a W-identification step. For a level playing field, we construct a W candidate from the three leading subjets by taking the pair of subjets with the smallest invariant mass; in the case that only two subjets are reconstructed, we take the mass of the leading subjet. All of the above taggers and groomers incorporate a step to remove pile-up and other soft radiation.

We also consider the performance of jet shape observables. In particular, we consider the N-subjettiness ratios $\tau_{32}^{\beta=1}$ and $\tau_{21}^{\beta=1}$, energy correlation function ratios $C_3^{\beta=1}$ and $C_2^{\beta=1}$, and the Qjet mass volatility Γ . In addition to the jet shape performance, we combine the jet shapes with the mass-reconstruction methods listed above to determine the optimal combined performance.

For determining the performance of multiple variables, we combine the relevant tagger output observables and/or jet shapes into a boosted decision tree (BDT), which determines the optimal cut. Additionally, because each tagger has two inputs (list, or maybe refer back to Section 3), we scan over reasonable values of the inputs to determine the optimal value for each top tagging signal efficiency. This allows a direct comparison of the optimized version of each tagger. The input values scanned for the various algorithms are:

```
We consider top quarks with moderate boost (600-822 1000 GeV), and perhaps most interestingly, at high boost (\gtrsim 1500 GeV). Top tagging faces several chal-823 lenges in the high-p_T regime. For such high-p_T jets,824 the b-tagging efficiencies are no longer reliably known.825 Also, the top jet can also accompanied by additional826

7.2 Single-observable performance

We start by investigating the behaviour of individuals⁸¹ jet substructure observables. Because of the rich, three-82 pronged structure of the top decay, it is expected that⁸³ combinations of masses and jet shapes will far out-84 perform single observables in identifying boosted tops.⁸⁵ However, a study of the top-tagging performance of sin-86 gle variables facilitates a direct comparison with the W_{87} tagging results in Section 6, and also allows a straight-88 forward examination of the performance of each observ-89 able for different p_T and jet radius.

Fig. 28 shows the ROC curves for each of the top-891 tagging observables, with the bare jet mass also plot-892 ted for comparison. Unlike W tagging, the jet shape⁸⁹³ observables perform more poorly than jet mass. As an⁸⁹⁴ example illustrating why this is the case, consider N_{-895} subjettiness. The W is two-pronged and the top is three 896 pronged; therefore, we expect τ_{21} and τ_{32} to be the best-897 performant N-subjettiness ratio, respectively. However, 898 τ_{21} also contains an implicit cut on the denominator, 899 τ_1 , which is strongly correlated with jet mass. There-900 fore, τ_{21} combines both mass and shape information to⁹⁰¹ some extent. By contrast, and as is clear in Fig.28(a),902 the best shape for top tagging is τ_{32} , which contains⁹⁰³ no information on the mass. Therefore, it is unsurpris-904 ing that the shapes most useful for top tagging are less⁹⁰⁵ sensitive to the jet mass, and under-perform relative to⁹⁰⁶ the corresponding observables for W tagging.

Of the two top tagging algorithms, the Johns Hop-908 kins (JH) tagger out-performs the HEPTopTagger in 909 its signal-to-background separation of both the top and 910 W candidate masses, with larger discrepancy at higher⁹¹¹ p_T and larger jet radius. In Fig. 29, we show the his-912 tograms for the top mass output from the JH and HEP-913 TopTagger for different R (Fig. 29) and p_T (30), opti-914 mized at a signal efficiency of 30%. The likely reason for⁹¹⁵ this behavior is that, in the HEPTopTagger algorithm, 916 the jet is filtered to select the five hardest subjets, and 917 then three subjets are chosen which reconstruct the top mass. This requirement tends to shape a peak in the QCD background around m_t for the HEPTopTagger,918 while the JH tagger has no such requirement. It has been suggested by Anders et al. [?] that performance 19 in the HEPTopTagger may be improved by selecting the 20 three subjets reconstructing the top only among those₂₂₁ that pass the W mass constraints, which somewhat re-922 duces the shaping of the background. Note that both₉₂₃ the JH tagger and the HEPTopTagger are superior at 924using the W candidate inside of the top for signal dis-925 crimination; this is because the the pruning and trim-926 ming algorithms do not have inherent W-identification 27 steps and are not optimized for this purpose.

We also directly compare the performance of top mass and jet shape observables for different jet p_T and radius. The input parameters of the taggers, groomers, and shape variables are separately optimized for each p_T and radius:

 p_T comparison: We compare various top tagging observables for jets in different p_T bins and R=0.8 in Figs. 31 and 34. The tagging performance of jet shapes do not change substantially with p_T . $\tau_{32}^{(\beta=1)}$ and the Qjet volatility Γ have the most variation and tend to degrade with higher p_T (see Fig. 32-33). This makes sense, as higher- p_T QCD jets have more, harder emissions within the jet, giving rise to substructure that fakes the signal. By contrast, most of the top mass observables have superior performance at higher p_T due to the radiation from the top quark becoming more collimated. The notable exception is the HEPTopTagger, which degrades at higher p_T , likely in part due to the background-shaping effects discussed earlier.

R comparison: We compare various top tagging observables for jets of different R and $p_T = 1.5 - 1.6$ TeV in Figs. 35-39. Most of the top-tagging parameters perform best for smaller radius; this is because, at such high p_T , most of the radiation from the top quark is confined within R = 0.4, and having a larger jet radius makes the observable more susceptible to contamination from the underlying event and other uncorrelated radiation. As we show in Figs. 36-38, the distributions for both signal broaden with increasing R, degrading the discriminating power. For $C_2^{(\beta=1)}$ and $C_3^{(\beta=1)}$, the background distributions are shifted upward as well. Therefore, the discriminating power generally gets worse with increasing R. The main exception is for $C_3^{(\beta=1)}$, which performs optimally at R=0.8; in this case, the signal and background coincidentally happen to have the same distribution around R = 0.4, and so R = 0.8 gives better discrimination.

7.3 Performance of multivariable combinations

We now consider various combinations of the observables from Section 7.2. In particular, we consider the performance of individual taggers such as the JH tagger and HEPTopTagger, which output information about the t and W candidate masses and the helicity angle; groomers, such as trimming and pruning, which remove soft, uncorrelated radiation from the top candidate to improve mass reconstruction, and to which we have added a W reconstruction step; and the combination of the above taggers/groomers with shape variables such

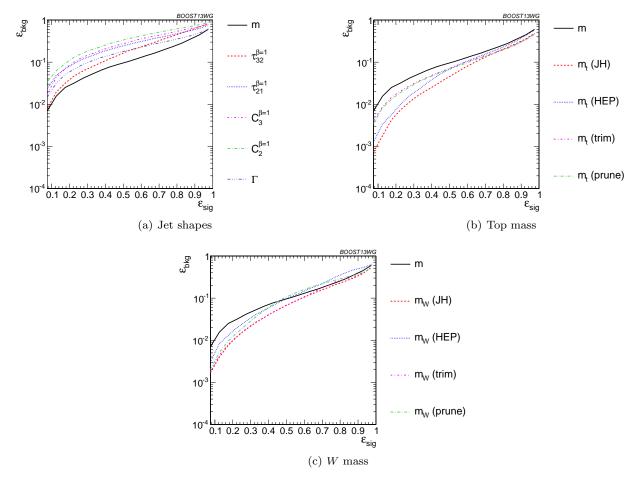

Fig. 28 Comparison of single-variable top-tagging performance in the $p_T = 1-1.1$ GeV bin using the anti- k_T , R=0.8 algorithm.

as N-subjettiness ratios and energy correlation ratios.950 For all observables with tuneable input parameters, websites scan and optimize over realistic values of such parame-952 ters. Our multivariate techniques are discussed in Sec-953 tion 4.

Fig. 40 shows our main results for the multivariable⁹⁵⁵ combinations; in all cases, we also show the ungroomed⁹⁵⁶ jet mass as a baseline comparison. In Fig. 40(a), we di-⁹⁵⁷ rectly compare the performance of the HEPTopTagger, ⁹⁵⁸ the JH tagger, trimming, and grooming. Generally, we ⁹⁵⁹ find that pruning, which does not naturally incorporate subjets into the algorithm, does not perform as well ⁹⁶¹ as the others. Interestingly, trimming, which does in-⁹⁶² clude a subjet-identification step, performs comparably ⁹⁶³ to the HEPTopTagger over much of the range, possi-⁹⁶⁴ bly due to the background-shaping observed in Section ⁹⁶⁵ 7.2. By contrast, the JH tagger outperforms the other ⁹⁶⁶ algorithms.

To determine whether there is complementary in-968 formation in the mass outputs from different top tag-969 gers, we also consider a multivariable combination of all₉₇₀

of the JH and HEPTopTagger outputs. The maximum efficiency of the combined JH and HEPTopTaggers is limited, as some fraction of signal events inevitably fails either one or other of the taggers. We do see a 20-50% improvement in performance when combining all outputs, which suggests that the different algorithms used to identify the t and W for different taggers contains complementary information.

In Fig. 40(b)-(d), we present the results for multivariable combinations of top tagger outputs with and without shape variables. We see that, for both the HEP-TopTagger and the JH tagger, the shape observables contain additional information uncorrelated with the masses and helicity angle, and give on average 2-3 improvement in signal discrimination. We see that, when combined with the tagger outputs, both the energy correlation functions C_2+C_3 and the N-subjettiness ratios $\tau_{21}+\tau_{32}$ give comparable performance, while the Qjet mass volatility is slightly worse; this is unsurprising, as Qjets accesses shape information in a more indirect way from other shape observables. Combining all shape ob-

974

975

976

977

978

We directly compare the performance of the JH and HEPTopTaggers in Fig. 40(d). Combining the taggers with shape information nearly erases the difference be-983 tween the tagging methods observed in Fig. 40(a); this had indicates that combining the shape information with HEPTopTagger identifies the differences between between the HEPTopTagger identifies the differences between the shape information with the HEPTopTagger identifies the differences between the shape information with the HEPTopTagger identifies the differences between the shape information with the shape information wi

signal and background missed by the tagger alone. This also suggests that further improvement to discriminating power may be minimal, as various multivariable combinations are converging to within a factor of 20% or so.

In Fig. 40(e)-(g), we present the results for multivariable combinations of groomer outputs with and without shape variables. As with the tagging algorithms,

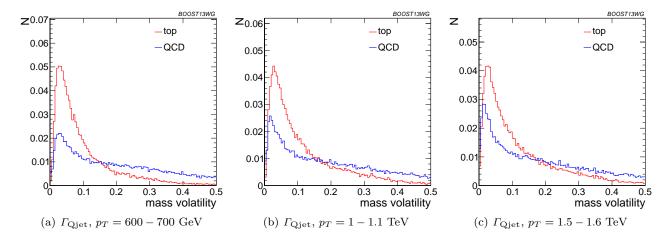

Fig. 32 Comparison of Γ_{Qjet} at R=0.8 and different values of the p_T .

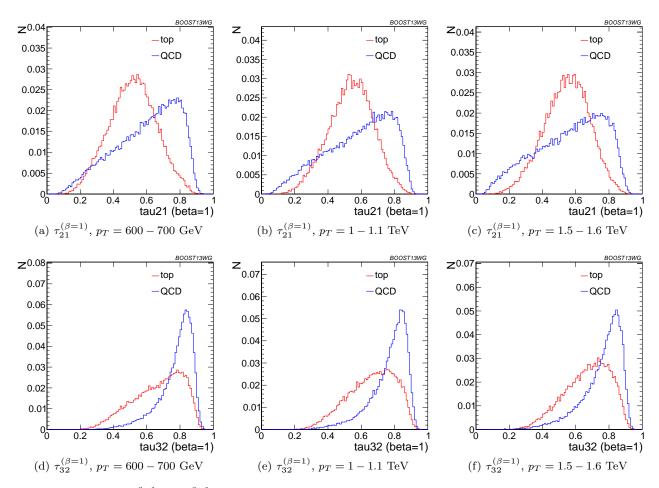

Fig. 33 Comparison of $\tau_{21}^{\beta=1}$ and $\tau_{32}^{\beta=1}$ with R=0.8 and different values of the p_T .

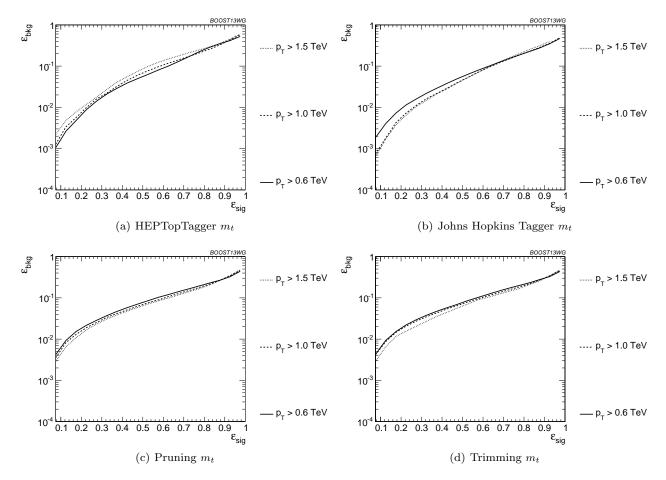

Fig. 34 Comparison of top mass performance of different taggers at different p_T using the anti- k_T R=0.8 algorithm.

combinations of groomers with shape observables im₁₀₀₀ proves their discriminating power; combinations with₁₀₁₀ $\tau_{32} + \tau_{21}$ perform comparably to those with $C_3 + C_{24011}$ and both of these are superior to combinations with₁₀₁₂ the mass volatility, Γ . Substantial improvement is fur₁₀₁₃ ther possible by combining the groomers with all shape₀₁₄ observables. Not surprisingly, the taggers that lag be₁₀₁₅ hind in performance enjoy the largest gain in signal₁₀₁₆ background discrimination with the addition of shape₁₀₁₇ observables. Once again, in 40(g), we find that the dif₁₀₁₈ ferences between pruning and trimming are erased when₁₀₁₉ combined with shape information.

 p_T comparison: We now compare the BDT combina_{t022} tions of tagger outputs, with and without shape vari_{t023} ables, at different p_T . The taggers are optimized over₀₂₄ all input parameters for each choice of p_T and signal ef_{t025} ficiency. As with the single-variable study, we consider₀₂₆ anti- k_T jets clustered with R=0.8 and compare the₀₂₇ outcomes in the $p_T=500-600$ GeV, $p_T=1-1.1$ TeV₄₀₂₈ and $p_T=1.5-1.6$ TeV bins. The comparison of the tag_{t029} gers/groomers is shown in Fig. 41. The behaviour with₀₃₀

 p_T is qualitatively similar to the behaviour of the m_t observable for each tagger/groomer shown in Fig. 34; this suggests that the p_T behaviour of the taggers is dominated by the top mass reconstruction. As before, the HEPTopTagger performance degrades slightly with increased p_T due to the background shaping effect, while the JH tagger and groomers modestly improve in performance.

In Fig. 42, we show the p_T dependence of BDT combinations of the JH tagger output combined with shape observables. We find that the curves look nearly identical: the p_T dependence is dominated by the top mass reconstruction, and combining the tagger outputs with different shape observables does not substantially change this behaviour. The same holds true for trimming and pruning. By contrast, HEPTopTagger ROC curves, shown in Fig. 43, do change somewhat when combined with different shape observables; due to the suboptimal performance of the HEPTopTagger at high p_T , we find that combining the HEPTopTagger with $C_3^{(\beta=1)}$, which in Fig. 31(b) is seen to have some modest improvement at high p_T , can improve its perfor-

R comparison: We now compare the BDT combina¹⁰⁴³ tions of tagger outputs, with and without shape vari¹⁰⁴⁴ ables, at different R and $p_T = 1.5 - 1.6$ TeV. The tag¹⁰⁴⁵ gers are optimized over all input parameters for each¹⁰⁴⁶

choice of R and signal efficiency, with the results shown in Fig. 44. We find that, for all taggers and groomers, the performance is always best at small R; the choice of R is sufficiently large to admit the full top quark decay at such high p_T , but is small enough to suppress contamination from additional radiation. This is not altered when the taggers are combined with shape observables; for example, in the case of the JH tagger

7.4 Performance at Sub-Optimal Working Points

Up until now, we have re-optimized our tagger and q_{081} groomer parameters for each p_T , R, and signal efficiency working point. In reality, experiments will choose a fi_{1083} nite set of working points to use. How do our results hold up when this is taken into account?

To address this concern, we replicate our analyses, but only optimize the top taggers for a particular $p_T/R/\text{efficiency}$ and apply the same parameters to
other scenarios. This allows us to determine the extent to which re-optimization is necessary to maintain
the high signal-background discrimination power seen
in the top tagging algorithms we study.

The shape observables typically do not have any input parameters to optimize. Therefore, we focus on the taggers and groomers, and their combination with shape observables, in this section.

Optimizing at a single p_T : We show in Fig. 46 the₁₂₁ performance of the top taggers with all input parame₁₁₂₂ ters optimized to the $p_T = 1.5 - 1.6$ TeV relative to the₁₂₃

performance optimized at each p_T . We see that while the performance degrades by about 50% when the high p_T optimized points are used at other momenta, this is only an O(1) adjustment of the tagger performance, with trimming and the Johns Hopkins tagger degrading the most. The jagged behaviour of the points is due to the finite resolution of the scan. We also observe a particular effect associated with using suboptimal taggers: since taggers sometimes fail to return a top candidate, parameters optimized for a particular efficiency ε_S at $p_T = 1.5 - 1.6$ TeV may not return enough signal candidates to reach the same efficiency at a different p_T . Consequently, no point appears for that p_T value. This is not often a practical concern, as the largest gains in signal discrimination and significance are for smaller values of ε_S , but it is something that must be considered when selecting benchmark tagger parameters and signal efficiencies.

The degradation in performance is more pronounced for the BDT combinations of the full tagger outputs (see Fig. 47), particularly at very low signal efficiency where the optimization picks out a cut on the tail of some distribution that depends precisely on the p_T/R of the jet. Once again, trimming and the Johns Hopkins tagger degrade more markedly.

Similar behaviour holds for the BDT combinations of taggers + shape observables, although we do not show the plots here because they look similar to Fig. 47.

Optimizing at a single R:

We perform a similar analysis, optimizing tagger parameters for each signal efficiency at R=1.2, and then use the same parameters for smaller R. We show the ratio of the performance of the top taggers with all input parameters optimized to the R=1.2 values compared to input parameters optimized separately at each radius, in Fig. 48. While the performance of each observable degrades at small $\epsilon_{\rm sig}$ compared to the optimized search, the HEPTopTagger fares the worst as the observed is quite sensitive to the selected value of R. It is not surprising that a tagger whose top mass reconstruction is susceptible to background-shaping at large R and p_T would require a more careful optimization of parameters to obtain the best performance.

The same holds true for the BDT combinations of the full tagger outputs (see Fig. 49). The performance for the sub-optimal taggers is still within an O(1) factor of the optimized performance, and the HEPTop-Tagger performs better with the combination of all of its outputs relative to the performance with just m_t . The same behaviour holds for the BDT combinations of tagger outputs and shape observables.

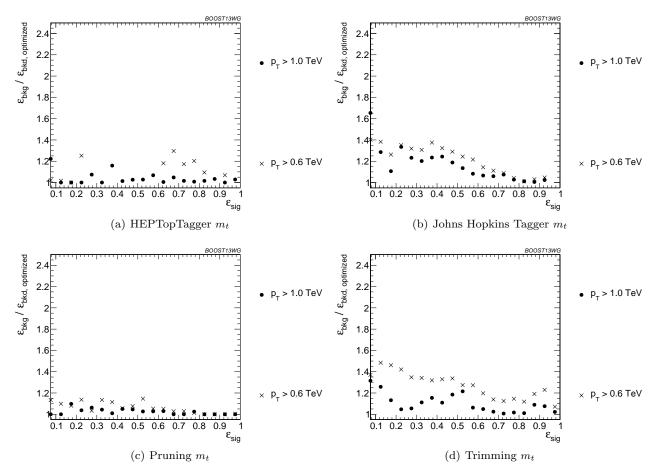

Fig. 46 Comparison of top mass performance of different taggers at different p_T using the anti- k_T R=0.8 algorithm; the tagger inputs are set to the optimum value for $p_T = 1.5 - 1.6$ TeV.

Optimizing at a single efficiency:

The strongest assumption we have made so far is 1814 that the taggers can be reoptimized for each signal effil147 ciency point. This is useful for making a direct compar 1148 ison of different top tagging algorithms, but is not par 1149 ticularly practical for the LHC analyses. We now consider the effects when the tagger inputs are optimized once, in the $\varepsilon_S=0.3-0.35$ bin, and then used to determine the full ROC curve. We do this at $p_T=1-1.1$ TeV and with R=0.8.

The performance of each tagger, normalized to its performance optimized in each bin, is shown in Fig. 50 for cuts on the top mass and W mass, and in Fig. 51 for BDT combinations of tagger outputs and shape variables. In both plots, it is apparent that optimizing the taggers in the 0.3-0.35 efficiency bin gives comparable performance over efficiencies ranging from 0.2-0.5, although performance degrades at small and large signal efficiencies. Pruning appears to give especially robust signal/background discrimination without re-optimization, possibly due to the fact that there are no absolute

distance or p_T scales that appear in the algorithm. Figs. 50-51 suggest that, while optimization at all signal efficiencies is a useful tool for comparing different algorithms, it is not crucial to achieve good top-tagging performance in experiments.

We thank the Department of Physics at the University of Arizona and for hosting the conference at the Little America Hotel. We also thank Harvard University for hosting the event samples used in this report. This work was made possible in part by the facilities of the Shared Hierarchical Academic Research Computing Network (SHARCNET) and Compute/Calcul Canada. We also thank Hallie Bolonkin for the BOOST2013 poster design and Jackson Boelts' ART465 class (fall 2012) at the University of Arizona School of Arts VisCom program. (NEED TO ASK PETER LOCH FOR MORE ACKNOWLEDGEMENTS)
