- Abstract Abstract for BOOST2013 report
- 2 Keywords boosted objects · jet substructure ·
- 3 beyond-the-Standard-Model physics searches · Large
- Hadron Collider

5 1 Introduction

The characteristic feature of collisions at the LHC is a 54 center-of-mass energy, 7 TeV in 2010 and 2011, of 8 TeV 55 in 2012, and near 14 TeV with the start of the second 56 phase of operation in 2015, that is large compared to 57 even the heaviest of the known particles. Thus these 58 particles (and also previously unknown ones) will often 59 be produced at the LHC with substantial boosts. As a 60 12 result, when decaying hadronically, these particles will 61 not be observed as multiple jets in the detector, but 62 14 rather as a single hadronic jet with distinctive internal 15 substructure. This realization has led to a new era of 16 sophistication in our understanding of both standard 63 17 QCD jets and jets containing the decay of a heavy particle, with an array of new jet observables and detection 64 19 techniques introduced and studies. To allow the efficient 65 sharing of results from these jet substructure studies a $^{66}\,$ 21 series of BOOST Workshops have been held on a yearly 67 basis: SLAC (2009, [?]), Oxford University (2010, [?]), 23 Princeton University University (2011, [?]), IFIC Va-24 lencia (2012 [?]), University of Arizona (2013 [?]), and, 25 most recently, University College London (2014 $\ref{201}$). Af- $\ref{10}$ 26 ter each of these meetings Working Groups have func- $^{72}\,$ tioned during the following year to generate reports 73 28 highlighting the most interesting new results, includ-74 ing studies of ever maturing details. Previous BOOST 75 30 reports can be found at [1,2,3]. 31

The following report from BOOST 2013 thus views ⁷⁷ the study and implementation of jet substructure techniques as a fairly mature field. The report attempts to ⁷⁹ focus on the question of the correlations between the ⁸⁰ plethora of observables that have been developed and ⁸¹ employed, and their dependence on the underlying jet ⁸² parameters, especially the jet radius R and jet p_T . The ⁸³ report is organized as follows: NEED TO GENERATE ⁸⁴ AN OUTLINE OF THE REPORT - ESPECIALLY AS I UNDERSTAND IT MYSELF.

2 Monte Carlo Samples and Event Selection

 $_{43}$ 2.1 Quark/gluon and W tagging

32

33

34

35

37

39

Samples were generated at $\sqrt{s} = 8$ TeV for QCD dijets, and for W^+W^- pairs produced in the decay of

a (pseudo) scalar resonance and decaying hadronically. The QCD events were split into subsamples of gg and $q\bar{q}$ events, allowing for tests of discrimination of hadronic W bosons, quarks, and gluons.

Individual gg and $q\bar{q}$ samples were produced at leading order (LO) using Madgraph5, while W^+W^- samples were generated using the JHU Generator to allow for separation of longitudinal and transverse polarizations. Both were generated using CTEQ6L1 PDFs[REF]. The samples were produced in exclusive p_T bins of width 100 GeV, with the slicing parameter chosen to be the p_T of any final state parton or W at LO. At the parton-level the p_T bins investigated were 300-400 GeV, 500-600 GeV and 1.0-1.1 TeV. Since no matching was performed, a cut on any parton was equivalent. The samples were then all showered through Pythia8 (version 8.176) using the default tune 4C.

2.2 Top tagging

Samples were generated at $\sqrt{s}=14$ TeV. Standard Model dijet and top pair samples were produced with Sherpa 2.0.0[REF], with matrix elements of up to two extra partons matched to the shower. The top samples included only hadronic decays and were generated in exclusive p_T bins of width 100 GeV, taking as slicing parameter the maximum of the top/anti-top p_T . The QCD samples were generated with a cut on the leading parton-level jet p_T , where parton-level jets are clustered with the anti- k_t algorithm and jet radii of $R=0.4,\,0.8,\,1.2$. The matching scale is selected to be $Q_{\rm cut}=40,60,80$ GeV for the $p_{T\,{\rm min}}=600,1000,$ and 1500 GeV bins, respectively.

The analysis again relies on FASTJET 3.0.3 for jet clustering and calculation of jet substructure observables, and an upper and lower p_T cut are applied to each sample to ensure similar p_T spectra in each bin. The bins in leading jet p_T that are investigated for top tagging are 600-700 GeV, 1-1.1 TeV, and 1.5-1.6 TeV. **ED:** What jet algorithm is used to define the p_T bins?

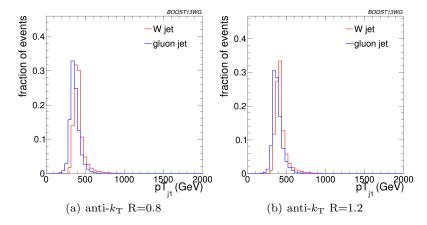

Fig. 1 Comparisons of the leading jet p_T spectrum of the gg background to the WW signal in the p_T 300-400 GeV parton p_T slice using the different anti- k_T jet distance parameters explored in this p_T bin. These distributions are formed prior to the 300-400 GeV leading jet p_T requirement.

119

3 Jet Algorithms and Substructure Observables

In this section, we define the jet algorithms and observables used in our analysis. Over the course of our study, 87 we considered a larger set of observables, but for the fi-88 nal analysis, we eliminated redundant observables for 89 presentation purposes. In Sections 3.1, 3.2, 3.3 and $3.4^{'''}_{112}$ 90 we first describe the various jet algorithms, groomers, taggers and other substructure variables used in these 92 studies, and then in Section 3.5 list which observables are considered in each section of this report, and the 94 exact settings of the parameters used.

6 3.1 Jet Clustering Algorithms

98

99

100

101

103

105

107

108

109

110

Jet clustering: Jets were clustered using sequential¹²¹ jet clustering algorithms [REF]. Final state particles i,¹²² j are assigned a mutual distance d_{ij} and a distance to the beam, $d_{i\rm B}$. The particle pair with smallest d_{ij} are recombined and the algorithm repeated until the¹²³ smallest distance is instead the distance to the beam, $d_{i\rm B}$, in which case i is set aside and labelled as a jet. The distance metrics are defined as

$$d_{ij} = \min(p_{Ti}^{2\gamma}, p_{Tj}^{2\gamma}) \frac{\Delta R_{ij}^2}{R^2}, \tag{1}$$

$$d_{iB} = p_{T_i}^{2\gamma},\tag{2}$$

where $\Delta R_{ij}^2 = (\Delta \eta)^2 + (\Delta \phi)^2$. In this analysis, we use₁₂₄ the anti- k_t algorithm $(\gamma = -1)$, the Cambridge/Aachen₁₂₅ (C/A) algorithm $(\gamma = 0)[\mathbf{REF}]$, and the k_t algorithm₁₂₆ $(\gamma = 1)[\mathbf{REF}]$, each of which has varying sensitivity to₁₂₇ soft radiation in defining the jet.

Qjets: We also perform non-deterministic jet cluster-130 ing[**REF**]. Instead of always clustering the particle pair131

with smallest distance d_{ij} , the pair selected for combination is chosen probabilistically according to a measure

$$P_{ij} \propto e^{-\alpha (d_{ij} - d_{\min})/d_{\min}},\tag{3}$$

where $d_{\rm min}$ is the minimum distance for the usual jet clustering algorithm at a particular step. This leads to a different cluster sequence for the jet each time the Qjet algorithm is used, and consequently different substructure properties. The parameter α is called the rigidity and is used to control how sharply peaked the probability distribution is around the usual, deterministic value. The Qjets method uses statistical analysis of the resulting distributions to extract more information from the jet than can be found in the usual cluster sequence. We use $\alpha=0.1$ and 25 trees per event for all the studies presented here.

3.2 Jet Grooming Algorithms

Pruning: Given a jet, re-cluster the constituents using the C/A algorithm. At each step, proceed with the merger as usual unless both

$$\frac{\min(p_{Ti}, p_{Tj})}{p_{Tij}} < z_{\text{cut}} \text{ and } \Delta R_{ij} > \frac{2m_j}{p_{Tj}} R_{\text{cut}}, \tag{4}$$

in which case the merger is vetoed and the softer branch discarded. The default parameters used for pruning [REF]in this study are $z_{\rm cut}=0.1$ and $R_{\rm cut}=0.5$. One advantage of pruning is that the thresholds used to veto soft, wide-angle radiation scale with the jet kinematics, and so the algorithm is expected to perform comparably over a wide range of momenta.

Trimming: Given a jet, re-cluster the constituents into $_{164}$ subjets of radius R_{trim} with the k_t algorithm. Discard all subjets i with

$$p_{Ti} < f_{\text{cut}} \, p_{TJ}.$$
 (5)

The default parameters used for trimming [**REF**] in this tudy are $R_{\text{trim}} = 0.2$ and $f_{\text{cut}} = 0.03$.

Filtering:[REF] Given a jet, re-cluster the constituents⁷² into subjets of radius $R_{\rm filt}$ with the C/A algorithm. Re-¹⁷³ define the jet to consist of only the hardest N subjets,¹⁷⁴ where N is determined by the final state topology and ¹⁷⁵ is typically one more than the number of hard prongs in ¹⁷⁶ the resonance decay (to include the leading final-state ¹⁷⁷ gluon emission). ED: Do we actually use filtering ¹⁷⁸ as described here anywhere?

Soft drop: Given a jet, re-cluster all of the constituents¹⁸¹ using the C/A algorithm. Iteratively undo the last stage¹⁸² of the C/A clustering from j into subjets j_1 , j_2 . If

$$\frac{\min(p_{T1}, p_{T2})}{p_{T1} + p_{T2}} < z_{\text{cut}} \left(\frac{\Delta R_{12}}{R}\right)^{\beta}, \tag{6}$$

discard the softer subjet and repeat. Otherwise, take j_{188}^{160} to be the final soft-drop jet[**REF**]. Soft drop has two input parameters, the angular exponent β and the soft-drop scale z_{cut} , with default value $z_{\text{cut}} = 0.1$. **ED: Soft-drop actually functions as a tagger when** $\beta = -1^{191}$

3.3 Jet Tagging Algorithms

133

134

135

137

138

139

140

141

142

143

145

146

147

151

152

153

154

155

156

157

158

160

161 162 **Modified Mass Drop Tagger:** Given a jet, re-cluster¹⁹⁶ all of the constituents using the C/A algorithm. Itera-¹⁹⁷ tively undo the last stage of the C/A clustering from j^{198} into subjets j_1 , j_2 with $m_{j_1} > m_{j_2}$. If either

$$m_{j_1} > \mu \, m_j \text{ or } \frac{\min(p_{T1}^2, p_{T2}^2)}{m_j^2} \, \Delta R_{12}^2 < y_{\text{cut}},$$
 (7)²⁰¹

then discard the branch with the smaller transverse mass $m_T = \sqrt{m_i^2 + p_{Ti}^2}$, and re-define j as the branch with the larger transverse mass. Otherwise, the jet is tagged. If de-clustering continues until only one branch remains, the jet is untagged. In this study we use by default $\mu = 1.0$ and $y_{\rm cut} = 0.1$.

Johns Hopkins Tagger: Re-cluster the jet using the ²¹⁰ C/A algorithm. The jet is iteratively de-clustered, and at each step the softer prong is discarded if its $p_{\rm T}$ is₂₁₁ less than $\delta_p \, p_{\rm T\, jet}$. This continues until both prongs are harder than the $p_{\rm T}$ threshold, both prongs are softer than the $p_{\rm T}$ threshold, or if they are too close $(|\Delta \eta_{ij}| + |\Delta \phi_{ij}| < \delta_R)$; the jet is rejected if either of the latter

conditions apply. If both are harder than the $p_{\rm T}$ threshold, the same procedure is applied to each: this results in 2, 3, or 4 subjets. If there exist 3 or 4 subjets, then the jet is accepted: the top candidate is the sum of the subjets, and W candidate is the pair of subjets closest to the W mass. The output of the tagger is m_t , m_W , and $\theta_{\rm h}$, a helicity angle defined as the angle, measured in the rest frame of the W candidate, between the top direction and one of the W decay products. The two free input parameters of the John Hopkins tagger in this study are δ_p and δ_R , defined above.

HEPTopTagger: Re-cluster the jet using the C/A algorithm. The jet is iteratively de-clustered, and at each step the softer prong is discarded if $m_1/m_{12} > \mu$ (there is not a significant mass drop). Otherwise, both prongs are kept. This continues until a prong has a mass $m_i < m$, at which point it is added to the list of subjets. Filter the jet using $R_{\text{filt}} = \min(0.3, \Delta R_{ij})$, keeping the five hardest subjets (where ΔR_{ij} is the distance between the two hardest subjets). Select the three subjets whose invariant mass is closest to m_t . The output of the tagger is m_t , m_W , and θ_h , a helicity angle defined as the angle, measured in the rest frame of the W candidate, between the top direction and one of the W decay products. The two free input parameters of the HEP-TopTagger in this study are m and μ , defined above.

Top Tagging with Pruning: For comparison with the other top taggers, we add a W reconstruction step to the trimming algorithm described above. A W candidate is found as follows: if there are two subjets, the highest-mass subjet is the W candidate (because the W prongs end up clustered in the same subjet); if there are three subjets, the two subjets with the smallest invariant mass comprise the W candidate. In the case of only one subjet, no W is reconstructed.

Top Tagging with Trimming: For comparison with the other top taggers, we add a W reconstruction step to the trimming algorithm described above. A W candidate is found as follows: if there are two subjets, the highest-mass subjet is the W candidate (because the W prongs end up clustered in the same subjet); if there are three subjets, the two subjets with the smallest invariant mass comprise the W candidate. In the case of only one subjet, no W is reconstructed.

3.4 Other Jet Substructure Observables

Qjet mass volatility: As described above, Qjet algorithms re-cluster the same jet non-deterministically to obtain a collection of interpretations of the jet. For

212

213 214

216

217

218

219

220

221

222

223

225

226

227

each jet interpretation, the pruned jet mass is computed230 with the default pruning parameters. The mass volatility, $\Gamma_{\rm Qjet}$, is defined as

$$\Gamma_{\text{Qjet}} = \frac{\sqrt{\langle m_J^2 \rangle - \langle m_J \rangle^2}}{\langle m_J \rangle},$$
(8)

where averages are computed over the Qjet interpreta- $_{\scriptscriptstyle{235}}$ tions.

N-subjettiness: N-subjettiness[REF] quantifies how $\frac{1}{238}$ well the radiation in the jet is aligned along N directions. To compute N-subjettiness, $au_N^{(\beta)}$, one must first identify N axes within the jet. Then,

$$\tau_N = \frac{1}{d_0} \sum_{i} p_{Ti} \min \left(\Delta R_{1i}^{\beta}, \dots, \Delta R_{Ni}^{\beta} \right), \tag{9}_{242}^{241}$$

where distances are between particles i in the jet and₂₄₄

$$d_0 = \sum_i p_{Ti} R^{\beta} \tag{10}^{246}$$

and R is the jet clustering radius. The exponent β is ²⁴⁸ a free parameter. There is also some choice in how^{249} the axes used to compute N-subjettiness are deter- 250 mined. The optimal configuration of axes is the $\mathrm{one}^{^{251}}$ that minimizes N-subjettiness; recently, it was shown²⁵² that the "winner-takes-all" axes can be easily computed²⁵³ and have superior performance compared to other min-254 imization techniques[REF]. ED: Do we use WTA?

Otherwise why do we mention this?

A more powerful discriminant is often the ratio,

$$\tau_{N,N-1} \equiv \frac{\tau_N}{\tau_{N-1}}. (11)^{258}$$

While this is not an infrared-collinear (IRC) safe ob-260 servable, it is calculable [REF] and can be made IRC261 safe with a loose lower cut on τ_{N-1} .

Energy correlation functions: The transverse momentum version of the energy correlation functions are defined as [REF]:

$$\mathrm{ECF}(N,\beta) = \sum_{i_1 < i_2 < \ldots < i_N \in j} \left(\prod_{a=1}^N p_{Ti_a} \right) \left(\prod_{b=1}^{N-1} \prod_{c=b+1}^N \Delta R_{ff}^{66} \right)^{267}$$

$$(12)^{268}$$

where i is a particle inside the jet. It is preferable to₂₇₀ work in terms of dimensionless quantities, particularly the energy correlation function double ratio:

$$C_N^{(\beta)} = \frac{\text{ECF}(N+1,\beta) \, \text{ECF}(N-1,\beta)}{\text{ECF}(N,\beta)^2}.$$
 (13)₂₇₃

This observable measures higher-order radiation from 275 leading-order substructure.

3.5 Observables for Each Analysis

Quark/gluon discrimination:

- The ungroomed jet mass, m.
- 1-subjettiness, τ_1^{β} with $\beta = 1, 2$. The N-subjettiness axes are computed using one-pass k_t axis optimiza-
- 1-point energy correlation functions, $C_1^{(\beta)}$ with $\beta =$
- The pruned Qjet mass volatility, Γ_{Qjet} .
- The number of constituents (N_{constits}) .

W vs. gluon discrimination:

- The ungroomed, trimmed (m_{trim}) , and pruned (m_{prun})
- The mass output from the modified mass drop tagger (m_{mmdt}) .
- The soft drop mass with $\beta = -1, 2 (m_{sd})$.
- 2-point energy correlation function ratio $C_2^{\beta=1}$ (we also studied $\beta = 2$ but did not show its results be-
- cause it showed poor discrimination power). N-subjettiness ratio τ_2/τ_1 with $\beta=1$ $(\tau_{21}^{\beta=1})$ and with axes computed using one-pass k_t axis optimization (we also studied $\beta = 2$ but did not show its results because it showed poor discrimination power).
- The pruned Qjet mass volatility.

Top vs. QCD discrimination:

The ungroomed jet mass.

257

- The HEPTopTagger and the Johns Hopkins tagger.
- Trimming and grooming supplemented with W candidate identification.
- N-subjettiness ratios τ_2/τ_1 and τ_3/τ_2 with $\beta=1$ and the "winner-takes-all" axes.
- 2-point energy correlation function ratios $C_2^{\beta=1}$ and
- The pruned Qjet mass volatility, $\Gamma_{\rm Qjet}$.

4 Multivariate Analysis Techniques

 $\mathrm{ECF}(N,\beta) = \sum_{i_1 < i_2 < \ldots < i_N \in j} \left(\prod_{a=1}^N p_{Ti_a}\right) \left(\prod_{b=1}^{N-1} \prod_{c=b+1}^N \Delta R_{bbi_c}^{sbi_c}\right)^{\beta} \frac{\text{Multivariate techniques are used to combine variables into an optimal discriminant. In all cases variables are combined using a boosted decision tree (BDT)}$ as implemented in the TMVA package [4]. We use the BDT implementation including gradient boost. An example of the BDT settings are as follows:

- NTrees=1000
- BoostType=Grad
- Shrinkage=0.1
- UseBaggedGrad=F
- nCuts=10000
- MaxDepth=3

5 Quark-Gluon Discrimination

In this section, we examine the differences between quarkand gluon-initiated jets in terms of substructure variables, and to determine to what extent these variables 334 are correlated. Along the way, we provide some theoretical understanding of these observables and their per-335 formance. The motivation for these studies comes not only from the desire to "tag" a jet as originating from 336 a quark or gluon, but also to improve our understand-337 ing of the quark and gluon components of the QCD338 backgrounds relative to boosted resonances. While re-339 cent studies have suggested that quark/gluon tagging340 efficiencies depend highly on the Monte Carlo generator341 used, we are more interested in understanding the scal-342 ing performance with p_T and R, and the correlations³⁴³ between observables, which are expected to be treated₃₄₄ consistently within a single shower scheme.

5.1 Methodology

These studies use the qq and gg MC samples, described₃₅₀ previously in Section 2. The showered events were clus-351 tered with FASTJET 3.03[REF] using the anti- $k_{\rm T}$ algo-352 rithm[REF] with jet radii of R = 0.4, 0.8, 1.2. In both₃₅₃ signal and background, an upper and lower cut on the354 leading jet p_T is applied after showering/clustering, to₃₅₅ ensure similar p_T spectra for signal and background in₃₅₆ each p_T bin. The bins in leading jet p_T that are inves-357 tigated in the W-tagging and q/g tagging studies are₃₅₈ 300-400 GeV, 500-600 GeV, 1.0-1.1 TeV. The distribu-359 tion of the leading jet p_T for the qq and WW samples₃₆₀ in the 300-400 GeV parton p_T slice prior to the require-361 ment on the leading jet p_T is shown in Figure 1, for the₃₆₂ R=0.8 and R=1.2 anti- $k_{\rm T}$ jet radii considered in this₃₆₃ p_T slice. Figures 2 and 3 show the equivalent leading₃₆₄ jet p_T distributions for the jet radii considered in the₃₆₅ $500\text{-}600~\mathrm{GeV}$ and 1.0 - $1.1~\mathrm{TeV}$ slices respectively. Var- $_{366}$ ious jet grooming approaches are applied to the jets, as₃₆₇ described in Section 3.4. Only leading and subleading₃₆₈ jets in each sample are used.

Figure 4 shows a comparison of the p_T and η dis-370 tributions of the quark and gluon samples with p_T =371 500 – 600 GeV. The differences in the p_T distributions372 can be attributed to different out-of-cone radiation pat-373 terns for quark and gluons; these differences becomes74

smaller as the R parameter is increased. The different η distributions are related to the different parton distribution functions initiating qq and gg production. The qualitative features of the η distributions do not change as the R parameter is changed. As the p_T increases, the η distributions peak more strongly near zero, as the probability peaks for processes initiated by partons of comparable energy. In our analysis, we make a narrow window cut of 100 GeV in p_T after showering, and so the effects of the different q/g p_T spectra on our analysis is suppressed. (**ED: check**)

5.2 Single Variable Discrimination

330

Figure 5 shows the mass of jets in the quark and gluon samples when using different groomers. Jets built with the anti- $k_{\rm T}$ algorithm with R=0.8 and with $p_T=500-650$ GeV are used (**BS:Check pT bins in this section!**). Qualitatively, the application of grooming shifts the mass distributions towards lower values as expected. No clear gain in discrimination can be seen, and for certain grooming parameters, such as the use of soft drop with $\beta=-1$ a clear loss in discrimination power is observed; this is because the soft-drop condition for $\beta=-1$ discards collinear radiation, and the differences between quarks and gluons are manifest in the collinear structure (spin, splitting functions, etc.).

The performance of different substructure variables is explored in Figure 6. Among those considered, n_{constits} provides the highest separation power, followed by $C_1^{\beta=0}$ and $C_1^{\beta=1}$ as was also found by the CMS and ATLAS Collaborations[**REF**].

To more quantitatively study the power of each observable as a discriminator for quark/gluon tagging, Receiver Operating Characteristic (ROC) curves are built by scanning each distribution and plotting the background efficiency (to select gluon jets) vs. the signal efficiency (to select quark jets). Figure 7 shows these ROC curves for all of the variables shown in Figure 6 and the ungroomed mass, representing the best performing mass variable, for jets of $p_T = 300 - 400$ GeV. In addition, we show the ROC curve for the tagger built from a BDT combining all the variables. The details of how the BDT is constructed are explained in Section 4. Clearly, n_{constits} is the best performing variable for all Rs, even though $C_1^{\beta=0}$ is close, particularly for R=0.8. Most other variables have similar performance, except the Q-jet volatility, which shows significantly worse discrimination (this may be due to our choice of rigidity $\alpha = 0.1$, while other studies suggest that a smaller value, such as $\alpha = 0.01$, produces better results). The combination of all variables shows somewhat better discrimination.

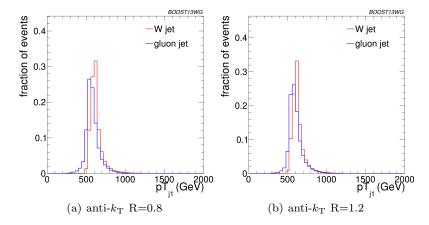

Fig. 2 Comparisons of the leading jet p_T spectrum of the gg background to the WW signal in the p_T 500-600 GeV parton p_T slice using the different anti- k_T jet distance parameters explored in this p_T bin. These distributions are formed prior to the 500-600 GeV leading jet p_T requirement.

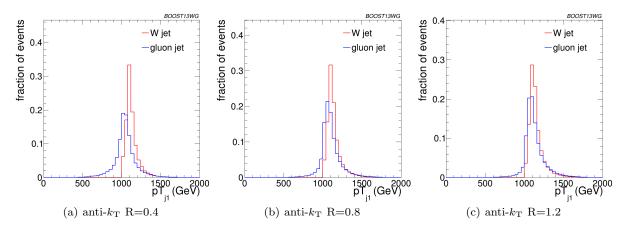

Fig. 3 Comparisons of the leading jet p_T spectrum of the gg background to the WW signal in the p_T 1.0-1.1 TeV parton p_T slice using the different anti- k_T jet distance parameters explored in this p_T bin. These distributions are formed prior to the 500-600 GeV leading jet p_T requirement.

We now examine how performance of masses and 92 substructure observables changes with p_T and R. For 93 jet masses, few variations are observed as the radius pa- 394 rameter of the jet reconstruction is increased in the two 395 highest p_T bins; this is because the radiation is more 396 collimated and the dependence on R is consequently 397 smaller. However, for the 300-400 GeV bin, the use of 398 small-R jets produces a shift in the mass distributions 399 towards lower values, so that large-R jet masses are more stable with p_T and small-R jet masses are smaller at low- p_T as expected from the spatial constraints imposed by the R parameter. These statements are explored more quantitatively later in this section. (BS: 404

The evolution of some of the substructure variable $_{406}$ distributions with p_T and R is less trivial than for the $_{407}$ jet masses. In particular, changing the R parameter at $_{408}$

high p_T changes significantly the C_a^{β} for $\beta>0$ and the $n_{\rm constits}$ distributions, while leaving all other distributions qualitatively unchanged. This is illustrated in Figure 8 for $\beta=0$ and $\beta=1$ using a=1 in both cases for jets with $p_T=1-1.2$ TeV.

The shift towards lower values with changing R is evident for the $C_1^{\beta=1}$ distributions, while the stability of $C_1^{\beta=0}$ can also be observed. These features are present in all p_T bins studied, but are even more pronounced for lower p_T bins. The shape of the Q-jet volatility distribution shows some non-trivial shape that deserves some explanation. Two peaks are observed, one at low volatility values and one at mid-volatility. These peaks are generated by two somewhat distinct populations. The high volatility peak arises from jets that get their mass primarily from soft (and sometimes wide-angle) emissions. The removal of some of the constituents when

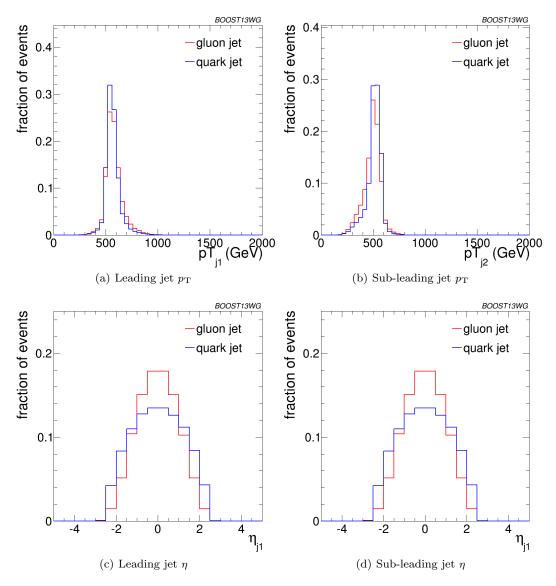

Fig. 4 Comparisons of quark and gluon p_T and η distributions in the sample used for the jets of $p_T = 500 - 600$ GeV bin using the anti- k_T R=0.8 algorithm.

building Q-jets thus changes the mass significantly, in- 423 creasing the volatility. The lower volatility peak cor- 424 responds to jets for which mass is generated by a hard emission, which makes the fraction of Q-jets that change the mass significantly to be smaller. Since the proba- 425 bility of a hard emission is proportional to the colour charge (squared), the volatility peak is higher for gluon 426 jets by about the colour factor C_A/C_F .

In summary, the overall discriminating power be-429 tween quarks and gluons decreases with increasing R₄₃₀ due to the reduction in the amount of out-of-cone radi-431 ation differences and and increased contamination from 432 the underlying event (**BS: is this ok?**). The broad per-433 formance features discussed for this p_T bin also apply434

to the higher p_T bins. These is further quantified in the next section.

5.3 Combined Performance and Correlations

The quark/gluon tagging performance can be further improved over cuts on single observables by combining multiple observables in a BDT; due to the challenging nature of q/g-tagging, any improvement in performance with multivariable techniques could be critical for certain analyses, and the improvement could be more substantial in data than the marginal benefit found in MC and shown in Fig. 7. Furthermore, insight can be gained into the features allowing for quark/gluon

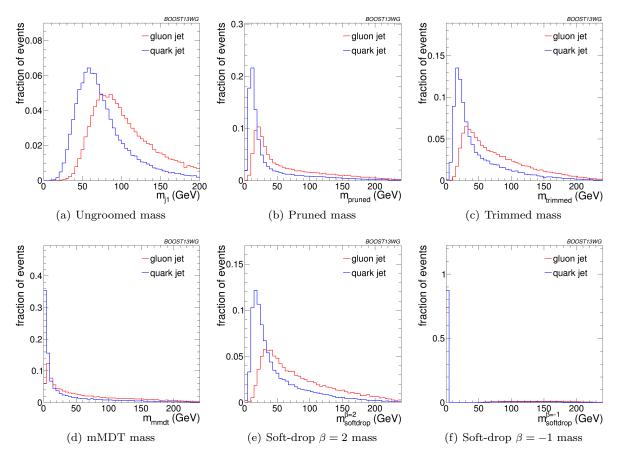

Fig. 5 Comparisons of ungroomed and groomed quark and gluon mass distributions for leading jets in the $p_T = 500 - 650$ GeV bin using the anti- $k_{\rm T}$ R=0.8 algorithm.

discrimination if the origin of the improvement is un- $_{457}$ derstood. To quantitatively study this improvement, we $_{458}$ build quark/gluon taggers from every pair-wise combi- $_{459}$ nation of variables studied in the previous section for $_{460}$ comparison with the all-variable combination.

In order to quantitatively study the value of each $^{\rm 462}$ variable for quark/gluon tagging, we study the gluon⁴⁶³ rejection, defined as $1/\epsilon_{\rm gluon}$, at a fixed quark selection⁴⁶⁴ efficiency of 50% using jets with $p_T = 1 - 1.2$ TeV and 465 for different R parameters. Figure 9 shows the gluon⁴⁶⁶ rejection for each pair-wise combination. The pair-wise467 gluon rejection at 50% quark efficiency can be compared 468 to the single-variable values shown along the diagonal.469 The gluon rejection for the BDT all-variable combina-470 tion is also shown on the bottom right of each plot. As₄₇₁ already observed in the previous section, n_{constits} is the most powerful single variable and $C_1^{(\beta=0)}$ follows closely.₄₇₃ However, the gains are largely correlated; the combined₄₇₄ performance of $n_{\rm constits}$ and $C_1^{(\beta=0)}$ is generally poorer₄₇₅ than combinations of $n_{\rm constits}$ with other jet substruc-476 ture observables, such as au_1 . Interestingly, in spite of the high correlation between $n_{\rm constits}$ and $C_1^{(\beta=0)}$, the two-478 variable combinations of $n_{\rm constits}$ generally fare worse than two-variable combinations with $C_1^{(\beta=0)}$. In particular, the combinations of $\tau_1^{\beta=1}$ or $C_1^{(\beta=1)}$ with $n_{\rm constits}$ are capable of getting very close to the rejection achievable through the use of all variables for R=0.4 and R=0.8.

Tagger performance is generally better at small R. The overall loss in performance with increasing R can be seen in most single variables we study; this is expected, since more of the parton radiation is captured in the jet and more contamination from underlying event occurs, suppressing the differences between q/g jets. The principal exceptions are $C_1^{(\beta=0)}$ and the Q-jet mass volatility, which are both quite resilient to increasing R. For $C_1^{(\beta=0)}$, this is due to the fact that the exponent on ΔR is zero, and so soft radiation at the periphery of the jet does not substantially change the distribution; as a result, the performance is largely independent of R. Similarly, the soft radiation distant from the jet centre will be vetoed during pruning regardless of the cluster sequence, and so the R-dependence of Γ_{Qjet} is not significant. (BS: Check my logic?) Their combination,

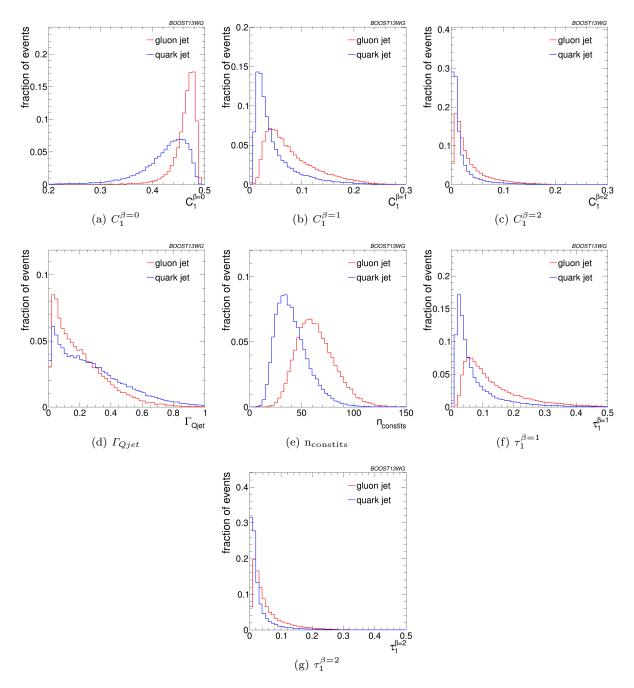

Fig. 6 Comparisons of quark and gluon distributions of different substructure variables for leading jets in the $p_T = 500 - 650$ GeV bin using the anti- k_T R=0.8 algorithm.

however, does perform slightly worse at larger R. (BS:487 I don't understand this, but it is a $\sim 10\%$ ef-488 fect, so maybe not too significant?). By contrast,489 $\tau_1^{(\beta=2)}$ and $C_1^{(\beta=2)}$ are particularly sensitive to increas-490 ing R since, for $\beta=2$, large-angle emissions are given⁴⁹¹ a larger weight.

480

481

482

483

484

485

486

These observations are qualitatively similar across⁴⁹⁴ all ranges of p_T . Quantitatively, however, there is a loss⁴⁹⁵

of rejection power for the taggers made of a combination of variables as the p_T decreases. This can be observed in Fig. 10 for anti- k_T R=0.4 jets of different p_T s. Clearly, most single variables retain their gluon rejection potential at lower p_T . However, when combined with other variables, the highest performing pairwise combinations lose ground with respect to other pairwise combinations. This is also reflected in the rejection of the tagger that uses a combination of all variables,

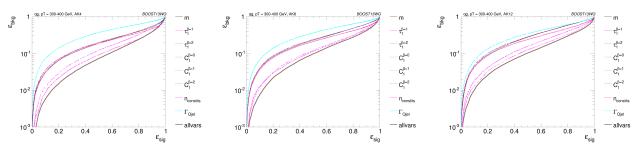

Fig. 7 The ROC curve for all single variables considered for quark-gluon discrimination in the p_T 500 GeV bin using the anti- k_T R=0.8 algorithm.

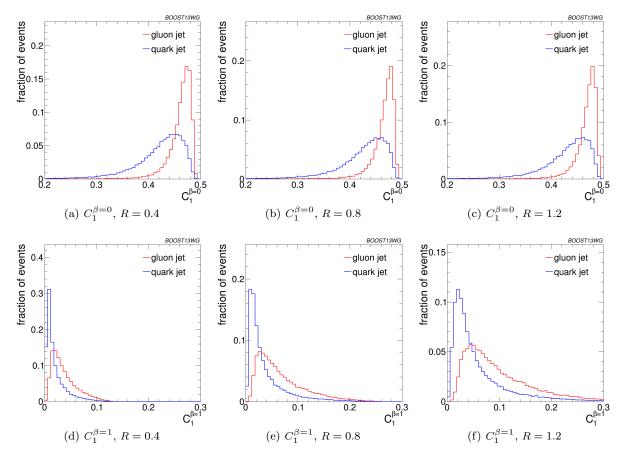

Fig. 8 Comparisons of quark and gluon distributions of $C_1^{\beta=0}$ (top) and $C_1^{\beta=1}$ (bottom) for leading jets in the $p_T = 1-1.2$ TeV bin using the anti- k_T algorithm with R = 0.4, 0.8 and 1.2.

which is lower at lower p_T s. [do we understand this?] (BS: This is a bit of a guess, but could it be that there is typically less radiation for low p_T , and so you're more sensitive to fluctuations; since you have less access to information, combinations of observables perform less well than at high p_T .)

In this section, we study the discrimination of a boosted $^{526}\,$ hadronically decaying W signal against a gluon background, comparing the performance of various groomed $^{^{528}}\!$ jet masses, substructure variables, and BDT combina- 529 tions of groomed mass and substructure. We produce 530 ROC curves that elucidate the performance of the vari- 531 ous groomed mass and substructure variables. A range $^{532}\,$ of different distance parameters R for the anti- $k_{\rm T}$ jet⁵³³ algorithm are explored, as well as a variety of kine- 534 matic regimes (lead jet p_T 300-400 GeV, 500-600 GeV, 535 1.0-1.1 TeV). This allows us to determine the perfor- 536 mance of observables as a function of jet radius and jet $^{537}\,$ boost, and to see where different approaches may break down. The groomed mass and substructure variables are then combined in a BDT as described in Section 4,538 and the performance of the resulting BDT discriminant explored through ROC curves to understand the degrees39 to which variables are correlated, and how this changes₅₄₀ with jet boost and jet radius.

6.1 Methodology

These studies use the WW samples as signal and the dijet gg samples to model the QCD background, as described previously in Section 2. Whilst only gluonic backgrounds are explored here, the conclusions as to the dependence of the performance and correlations on the jet boost and radius have been verified to hold also for qg backgrounds. **ED:** To be checked!

In each of the three p_T slices considered jets are reconstructed using the anti- k_T algorithm with distance parameter R=0.4, 0.8 and 1.2, as described in Section 2. They then have various grooming approaches applied as described in Section 3.5. (ED: Probably better if some of the information from Sections 2 and 3.5 is brought into this section to avoid this back-referencing.)

6.2 Single Variable Performance

In this section we will explore the performance of the various groomed jet mass and substructure variables in terms of discriminating signal and background, and how 543

this performance changes depending on the kinematics95 bin and jet radius considered.

Figure 11 the compares the signal and background 597 in terms of the different groomed masses explored for⁵⁹⁸ the anti- $k_{\rm T}$ R=0.8 algorithm in the p_T 500-600 bin. One can clearly see that in terms of separating signal and 600 background the groomed masses will be significantly⁶⁰¹ more performant than the ungroomed anti- $k_{\rm T}$ R=0.802 mass. Figure 12 compares signal and background in the the theory different substructure variables explored for the same of jet radius and kinematic bin.

Figures 13, 14 and 15 show the single variable ROC606 curves compared to the ROC curve for a BDT combi-607 nation of all the variables (labelled "allvars"), for each 608 of the anti- $k_{\rm T}$ distance parameters considered in each⁶⁰⁹ of the kinematic bins. One can see that, in all cases,610 the "allvars" option is considerably better performant⁶¹¹ than any of the individual single variables considered,612 indicating that there is considerable complementarity⁶¹³ between the variables, and this will be explored further⁶¹⁴ in the next section.

Although the ROC curves give all the relevant in-616 formation, it is hard to compare performance quanti-617 tatively. In Figures 16, 17 and 18 are shown matrices⁶¹⁸ which give the background rejection for a signal effi-619 ciency of 70% when two variables (that on the x-axis⁶²⁰ and that on the y-axis) are combined in a BDT. These⁶²¹ are shown separately for each p_T bin and jet radius considered. The diagonal of these plots correspond to the background rejections for a single variable BDT,622 and can thus be examined to get a quantitative measure of the individual single variable performance, and₆₂₃ to study how this changes with jet radius and momenta. 624

One can see that in general the most performante25 single variables are the groomed masses. However, in 626 certain kinematic bins and for certain jet radii, $C_2^{\beta=1}$ ₆₂₇ has a background rejection that is comparable to or628 better than the groomed masses.

By comparing Figures 16(a), 17(a) and 18(b), we⁵³⁰ can see how the background rejection performance evolves as we increase momenta whilst keeping the jet radius⁶³² fixed to R=0.8. Similarly, by comparing Figures 16(b), 14(b) variable combinations involve a groomed mass and a and 18(c) we can see how performance evolves with $p_{T^{634}}$ for R=1.2. For both R=0.8 and R=1.2 the background⁶³⁵ rejection power of the groomed masses increases with 636 increasing p_T , with a factor 1.5-2.5 increase in rejec-637 tion in going from the 300-400 GeV to 1.0-1.1 TeV bins.638 ED: Add some of the 1-D plots comparing sig-639 nal and bkgd in the different masses and pT bins $_{640}$ here? However, the $C_2^{\beta=1}$, Γ_{Qjet} and $\tau_{21}^{\beta=1}$ substructure₆₄₁ variables behave somewhat differently. The background₆₄₂ rejection power of the Γ_{Qjet} and $\tau_{21}^{\beta=1}$ variables both₆₄₃ decrease with increasing p_T , by up to a factor two-44

in going from the 300-400 GeV to 1.0-1.1 TeV bins. Conversely the rejection power of $C_2^{\beta=1}$ dramatically increases with increasing p_T for R=0.8, but does not improve with p_T for the larger jet radius R=1.2. **ED**: Can we explain this? Again, should we add some of the 1-D plots?

By comparing the individual sub-figures of Figures 16, 17 and 18 we can see how the background rejection performance depends on jet radius within the same p_T bin. To within $\sim 25\%$, the background rejection power of the groomed masses remains constant with respect to the jet radius. However, we again see rather different behaviour for the substructure variables. In all p_T bins considered the most performant substructure variable, $C_2^{\beta=1}$, performs best for an anti- $k_{\rm T}$ distance parameter of R=0.8. The performance of this variable is dramatically worse for the larger jet radius of R=1.2 (a factor seven worse background rejection in the 1.0-1.1 TeV bin), and substantially worse for R=0.4. For the other jet substructure variables considered, Γ_{Qjet} and $\tau_{21}^{\beta=1}$, their background rejection power also reduces for larger jet radius, but not to the same extent. ED: Insert some nice discussion/explanation of why jet substructure power generally gets worse as we go to large jet radius, but groomed mass performance does not. Probably need the 1-D figures for this.

6.3 Combined Performance

The off-diagonal entries in Figures 16, 17 and 18 can be used to compare the performance of different BDT two-variable combinations, and see how this varies as a function of p_T and R. By comparing the background rejection achieved for the two-variable combinations to the background rejection of the "all variables" BDT, one can understand how much more discrimination is possible by adding further variables to the two-variable BDTs.

One can see that in general the most powerful twonon-mass substructure variable $(C_2^{\beta=1}, \Gamma_{Qjet} \text{ or } \tau_{21}^{\beta=1}).$ Two-variable combinations of the substructure variables are not powerful in comparison. Which particular mass + substructure variable combination is the most powerful depends strongly on the p_T and R of the jet, as discussed in the sections that follow.

There is also modest improvement in the background rejection when different groomed masses are combined, compared to the single variable groomed mass performance, indicating that there is complementary information between the different groomed masses. In addition,

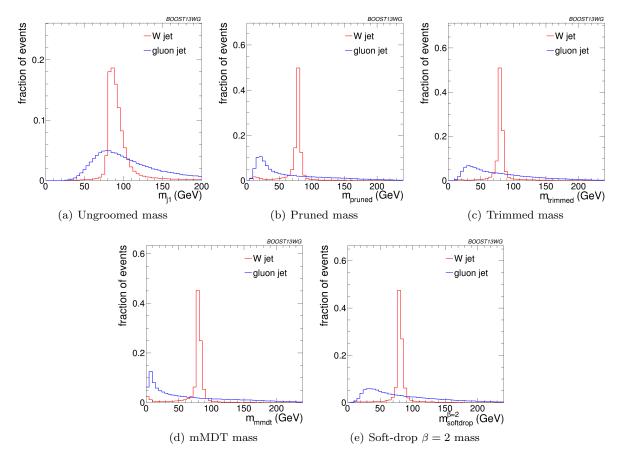

Fig. 11 Comparisons of the QCD background to the WW signal in the p_T 500-600 GeV bin using the anti- k_T R=0.8 algorithm: leading jet mass distributions.

there is an improvement in the background rejection when the groomed masses are combined with the un-666 groomed mass, indicating that grooming removes some useful discriminatory information from the jet. These observations are explored further in the section below.

Generally one can see that the R=0.8 jets offer the best two-variable combined performance in all p_T bins 2 explored here. This is despite the fact that in the high 2 est 1.0-1.1 GeV p_T bin the average separation of the 3 quarks from the W decay is much smaller than 0.8 4 and well within 0.4. This conclusion could of course be 3 susceptible to pile-up, which is not considered in this 3 study.

6.3.1 Mass + Substructure Performance

As already noted, the largest background rejection at 681 70% signal efficiency are in general achieved using those 82 two variable BDT combinations which involve a groome 68 mass and a non-mass substructure variable. For both 68 R=0.8 and R=1.2 jets, the rejection power of these two variable combinations increases substantially with in-686

creasing p_T , at least within the p_T range considered here.

For a jet radius of R=0.8, across the full p_T range considered, the groomed mass + substructure variable combinations with the largest background rejection are those which involve $C_2^{\beta=1}$. For example, in combination with $m_{sd}^{\beta=2}$, this produces a five-, eight- and fifteen-fold increase in background rejection compared to using the groomed mass alone. In Figure 19 the low degree of correlation between $m_{sd}^{\beta=2}$ versus $C_2^{\beta=1}$ that leads to these large improvements in background rejection can be seen. One can also see that what little correlation exists is rather non-linear in nature, changing from a negative to a positive correlation as a function of the groomed mass, something which helps to improve the background rejection in the region of the W mass peak.

However, when we switch to a jet radius of R=1.2 the picture for $C_2^{\beta=1}$ combinations changes dramatically. These become significantly less powerful, and the most powerful variable in groomed mass combinations becomes $\tau_{21}^{\beta=1}$ for all jet p_T considered. Figure 20 shows the correlation between $m_{sd}^{\beta=2}$ and $C_2^{\beta=1}$ in the p_T 1.0

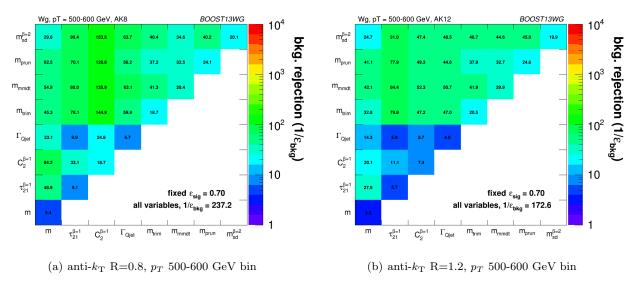

Fig. 17 The background rejection for a fixed signal efficiency (70%) of each BDT combination of each pair of variables considered, in the p_T 500-600 GeV bin using the anti- k_T R=0.8 algorithm and R=1.2 algorithm. Also shown is the background rejection for a BDT combination of all of the variables considered.

- 1.2 TeV bin for the various jet radii considered. Fig-697 ure 21 is the equivalent set of distributions for $m_{sd}^{\beta=2}$ 698 and $\tau_{21}^{\beta=1}$. One can see from Figure 20 that, due to the699 sensitivity of the observable to to soft, wide-angle ra-700 diation, as the jet radius increases $C_2^{\beta=1}$ increases and becomes more and more smeared out for both signal701 and background, leading to worse discrimination power. This does not happen to the same extent for $\tau_{21}^{\beta=1}$. We⁷⁰² can see from Figure 21 that the negative correlation be-703 tween $m_{sd}^{\beta=2}$ and $\tau_{21}^{\beta=1}$ that is clearly visible for R=0.4704

687

694

695

decreases for larger jet radius, such that the groomed mass and substructure variable are far less correlated and $\tau_{21}^{\beta=1}$ offers improved discrimination within a $m_{sd}^{\beta=2}$ mass window.

6.3.2 Mass + Mass Performance

The different groomed masses and the ungroomed mass are of course not fully correlated, and thus one can always see some kind of improvement in the background rejection (relative to the single mass performance) when

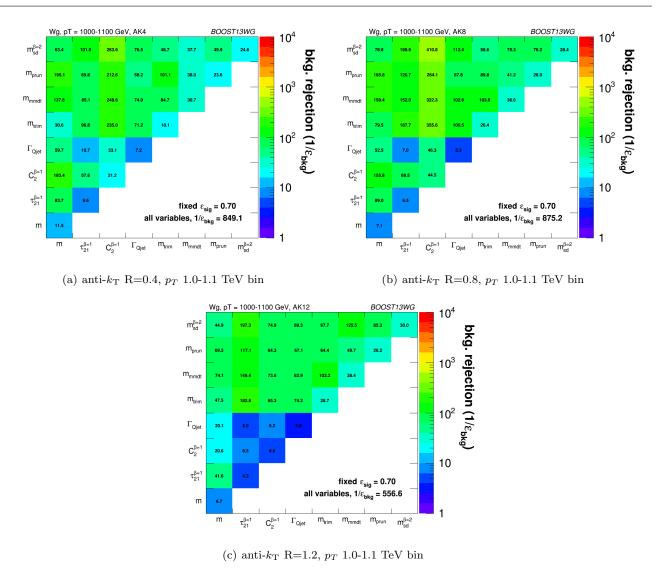

Fig. 18 The background rejection for a fixed signal efficiency (70%) of each BDT combination of each pair of variables considered, in the p_T 1.0-1.1 TeV bin using the anti- k_T R=0.4, R=0.8 and R=1.2 algorithm. Also shown is the background rejection for a BDT combination of all of the variables considered.

two different mass variables are combined in the BDT.₇₂₁ However, in some cases the improvement can be dra-₇₂₂ matic, particularly at higher p_T , and particularly for₇₂₃ combinations with the ungroomed mass. For example,₇₂₄ in Figure 18 we can see that in the p_T 1.0-1.1 TeV bin₇₂₅ the combination of pruned mass with ungroomed mass₇₂₆ produces a greater than eight-fold improvement in the₇₂₇ background rejection for R=0.4 jets, a greater than five-₇₂₈ fold improvement for R=0.8 jets, and a factor ~two im-₇₂₉ provement for R=1.2 jets. A similar behaviour can be₇₃₀ seen for mMDT mass. In Figures 22, 23 and 24 is shown₇₃₁ the 2-D correlation plots of the pruned mass versus the₇₃₂ ungroomed mass separately for the WW signal and gg₇₃₃ background samples in the p_T 1.0-1.1 TeV bin, for the₇₃₄ various jet radii considered. For comparison, the corre-₇₃₅

lation of the trimmed mass with the ungroomed mass, a combination that does not improve on the single mass as dramatically, is shown. In all cases one can see that there is a much smaller degree of correlation between the pruned mass and the ungroomed mass in the backgrounds sample than for the trimmed mass and the ungroomed mass. This is most obvious in Figure 22, where the high degree of correlation between the trimmed and ungroomed mass is expected, since with the parameters used (in particular $R_{trim} = 0.2$) we cannot expect trimming to have a significant impact on an R=0.4 jet. The reduced correlation with ungroomed mass for pruning in the background means that, once we have made the requirement that the pruned mass is consistent with a W (i.e. \sim 80 GeV), a relatively large difference be-

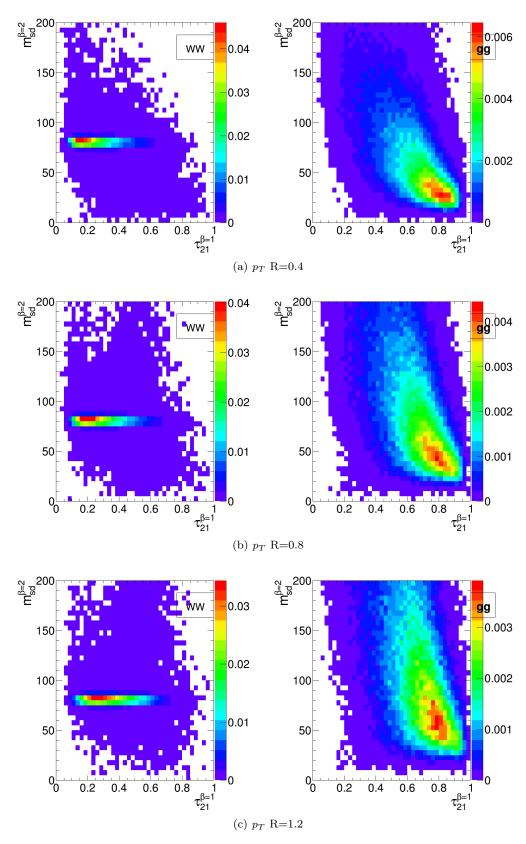

Fig. 21 2-D plots showing $m_{sd}^{\beta=2}$ versus $\tau_{21}^{\beta=1}$ for R=0.4, 0.8 and 1.2 jets in the p_T 1.0-1.1 TeV bin.

tween signal and background in the ungroomed mass still remains, and can be exploited to improve the background rejection further. In other words, many of the background events which pass the pruned mass requirement do so because they are shifted to lower mass (to be within a signal mass window) by the grooming, but these events still have the property that they look very much like background events before the grooming. A single requirement on the groomed mass only does not exploit this. Of course, the impact of pile-up, not considered in this study, could significantly limit the degree to which the ungroomed mass could be used to improve discrimination in this way.

6.3.3 "All Variables" Performance

As well as the background rejection at a fixed 70% signal efficiency for two-variable combinations, Figures 16, 17 and 18 also report the background rejection achieved by a combination of all the variables considered into a single BDT discriminant. One can see that, in all cases, the rejection power of this "all variables" BDT is significantly larger than the best two-variable combination, by between a factor 2-3. This indicates that beyond the best two-variable combination there is still significant complementary information available in the remaining variables in order to improve the discrimination of signal and background.

ED: This section will be filled in when we have got the 3-variable combination studies, so we have a better idea where the dramatic increase in rejection power with "all variables" is coming from. Would also be good to show perhaps some of the "all variables" BDT discriminants in 1-D plots.

radiation with $p_T \sim m_t$, leading to combinatoric ambiguities of reconstructing the top and W, and the possibility that existing taggers or observables shape the background by looking for subjet combinations that reconstruct m_t/m_W . To study this, we examine the performance of both mass-reconstruction variables, as well as shape observables that probe the three-pronged nature of the top jet and the accompanying radiation pattern.

7.1 Methodology

We study a number of top-tagging strategies, in partic-

- 1. HEPTopTagger
- 2. Johns Hopkins Tagger (JH) 797
 - 3. Trimming
 - 4. Pruning

The top taggers have criteria for reconstructing a top and W candidate, and a corresponding top and W mass, as described in Section 3.3, while the grooming algorithms (trimming and pruning) do not incorporate a W-identification step. For a level playing field, where grooming is used we construct a W candidate mass, m_W , from the three leading subjets by taking the mass of the pair of subjets with the smallest invariant mass; in the case that only two subjets are reconstructed, we take the mass of the leading subjet. The top mass, m_t , is the mass of the groomed jet. All of the above taggers and groomers incorporate a step to remove pile-up and other soft radiation.

We also consider the performance of jet shape observables. In particular, we consider the N-subjettiness ratios $au_{32}^{\beta=1}$ and $au_{21}^{\beta=1}$, energy correlation function ratios $C_3^{\beta=1}$ and $C_2^{\beta=1}$, and the Qjet mass volatility Γ . In addition to the jet shape performance, we combine the jet shapes with the mass-reconstruction methods described above to determine the optimal combined performance.

For determining the performance of multiple variables, we combine the relevant tagger output observables and/or jet shapes into a boosted decision tree (BDT), which determines the optimal cut. Additionally, because each tagger has two input parameters, as described in Section 3.3, we scan over reasonable values of the parameters to determine the optimal value for each top tagging signal efficiency. This allows a direct comparison of the optimized version of each tagger. The input values scanned for the various algorithms are:

```
We consider top quarks with moderate boost (600-828)
1000 GeV), and perhaps most interestingly, at high ^{829}
boost (\gtrsim 1500 GeV). Top tagging faces several chal-830
lenges in the high-p_T regime. For such high-p_T jets,<sup>831</sup>
the b-tagging efficiencies are no longer reliably known.<sup>832</sup>
Also, the top jet can also accompanied by additional<sup>833</sup>
```

- **HEPTopTagger:** $m \in [30, 100] \text{ GeV}, \mu \in [0.5, 1]$
- JH Tagger: $\delta_p \in [0.02, 0.15], \, \delta_R \in [0.07, 0.2]$ **Trimming:** $f_{\text{cut}} \in [0.02, 0.14], R_{\text{trim}} \in [0.1, 0.5]$
- **Pruning:** $z_{\text{cut}} \in [0.02, 0.14], R_{\text{cut}} \in [0.1, 0.6]$

In this section, we study the identification of boosted $_{802}$ top quarks at Run II of the LHC. Boosted top quarks $_{803}$ result in large-radius jets with complex substructure, 804 containing a b-subjet and a boosted W. The additional $_{805}$ kinematic handles coming from the reconstruction of $_{806}$ the W mass and b-tagging allows a very high degree $_{807}$ of discrimination of top quark jets from QCD back- $_{808}$ grounds.

7.2 Single-observable performance

We start by investigating the behaviour of individuals jet substructure observables. Because of the rich, three-899 pronged structure of the top decay, it is expected that combinations of masses and jet shapes will far out-891 perform single observables in identifying boosted tops.892 However, a study of the top-tagging performance of \sin_{-893} gle variables facilitates a direct comparison with the W_{894} tagging results in Section 6, and also allows a straight-895 forward examination of the performance of each observ-896 able for different p_T and jet radius.

Fig. 25 shows the ROC curves for each of the top-898 tagging observables, with the bare (ungroomed) jet massoo also plotted for comparison. The jet shape observables... all perform substantially worse than jet mass, unlike W_{901} tagging for which several observables are competitive⁹⁰² with or perform better than jet mass (see, for exam-903 ple, Fig. 11). To understand why this is the case, con-904 sider N-subjettiness. The W is two-pronged and the 005 top is three-pronged; therefore, we expect τ_{21} and $\tau_{32^{906}}$ to be the best-performant N-subjettiness ratio, respec-907 tively. However, τ_{21} also contains an implicit cut on the on denominator, τ_1 , which is strongly correlated with jetsoo mass. Therefore, τ_{21} combines both mass and shape in-910 formation to some extent. By contrast, and as is clear⁹¹¹ in Fig.25(a), the best shape for top tagging is τ_{32} , which 12 contains no information on the mass. Therefore, it is unsurprising that the shapes most useful for top tagging₉₁₄ are less sensitive to the jet mass, and under-perform rel- $_{915}$ ative to the corresponding observables for W tagging. $_{916}$

Of the two top tagging algorithms, we can see from₉₁₇ Figure 25 that the Johns Hopkins (JH) tagger out-918 performs the HEPTopTagger in terms of its signal-to-919 background separation power in both the top and W_{920} candidate masses. In Figure 26 we show the histograms₉₂₁ for the top mass output from the JH and HEPTopTag-922 ger for different R in the p_T 1.5-1.6 TeV bin, and in₉₂₃ Figure 27 for different p_T at at R =0.8, optimized at₉₂₄ a signal efficiency of 30%. One can see from these fig-925 ures that the likely reason for the better performance of 926 the JH tagger is that, in the HEPTopTagger algorithm, 927 $\,$ the jet is filtered to select the five hardest subjets, and 228 then three subjets are chosen which reconstruct the top₉₂₉ mass. This requirement tends to shape a peak in the 30 QCD background around m_t for the HEPTopTagger,931 while the JH tagger has no such requirement. It has 932 been suggested by Anders et al. [5] that performance in 333 the HEPTopTagger may be improved by selecting the934 three subjets reconstructing the top only among those 35 that pass the W mass constraints, which somewhate 36 reduces the shaping of the background. The discrep-937 ancy between the JH and HEPTopTaggers is more pro-938 nounced at higher p_T and larger jet radius (see Figs. 31 and 36). Note that both the JH tagger and the HEP-TopTagger are superior to the grooming algorithms at using the W candidate inside of the top for signal discrimination; this is because the pruning and trimming algorithms do not have inherent W-identification steps and are not optimized for this purpose.

In Figures 28 and 31 we directly compare ROC curves for jet shape observable performance and top mass performance respectively in the three different p_T bins considered whilst keeping the jet radius fixed at R=0.8. The input parameters of the taggers, groomers and shape variables are separately optimized in each p_T bin. One can see from Figure 28 that the tagging performance of jet shapes do not change substantially with p_T . The observables $\tau_{32}^{(\beta=1)}$ and Qjet volatility Γ have the most variation and tend to degrade with higher p_T , as can be seen in Figures 29 and 30). This makes sense, as higher- p_T QCD jets have more, harder emissions within the jet, giving rise to substructure that fakes the signal. By contrast, from Figure 31 we can see that most of the top mass observables have superior performance at higher p_T due to the radiation from the top quark becoming more collimated. The notable exception is the HEPTopTagger, which degrades at higher p_T , likely in part due to the background-shaping effects discussed earlier.

In Figures 32 and 36 we directly compare ROC curves for jet shape observable performance and top mass performance respectively for the three different jet radii considered within the p_T 1.5-1.6 TeV bin. Again, the input parameters of the taggers, groomers and shape variables are separately optimized for each jet radius. We can see from these figures that most of the top tagging variables, both shape and reconstructued top mass, perform best for smaller radius. This is likely because, at such high p_T , most of the radiation from the top quark is confined within R = 0.4, and having a larger jet radius makes the observable more susceptible to contamination from the underlying event and other uncorrelated radiation. In Figures 33, 34 and 35, we compare the individual top signal and QCD background distributions for each shape variable considered in the p_T 1.5-1.6 TeV bin for the various jet radii. One can see that the distributions for both signal broaden with increasing R, degrading the discriminating power. For $C_2^{(\beta=1)}$ and $C_3^{(\beta=1)}$, the background distributions are shifted upward as well. Therefore, the discriminating power generally gets worse with increasing R. The main exception is for $C_3^{(\beta=1)}$, which performs optimally at R = 0.8; in this case, the signal and background coincidentally happen to have the same distribution around R = 0.4, and so R = 0.8 gives better discrimination.

We now consider various BDT combinations of the ob-966 servables from Section 7.2, using the techniques de-967 scribed in Section 4. In particular, we consider the per-968 formance of individual taggers such as the JH tagger969 and HEPTopTagger, which output information about970 the top and W candidate masses and the helicity an-971 gle; groomers, such as trimming and pruning, which972 remove soft, uncorrelated radiation from the top can-973 didate to improve mass reconstruction, and to which974 we have added a W reconstruction step; and the com-975 bination of the outputs of the above taggers/groomers,976 both with each other, and with shape variables such as977 N-subjettiness ratios and energy correlation ratios. For978

all observables with tuneable input parameters, we scan and optimize over realistic values of such parameters, as described in Section 7.1.

In Figure 37, we directly compare the performance of the HEPTopTagger, the JH tagger, trimming, and pruning, in the $p_T = 1 - 1.1$ TeV bin using jet radius R=0.8, where both m_t and m_W are used in the groomers. Generally, we find that pruning, which does not naturally incorporate subjets into the algorithm, does not perform as well as the others. Interestingly, trimming, which does include a subjet-identification step, performs comparably to the HEPTopTagger over much of the range, possibly due to the background-shaping observed in Section 7.2. By contrast, the JH tagger outperforms the other algorithms. To determine whether there is complementary information in the mass outputs from different top taggers, we also consider in Figure 37 a multivariable combination of all of the JH and HEP-TopTagger outputs. The maximum efficiency of the combined JH and HEPTopTaggers is limited, as some fraction of signal events inevitably fails either one or other

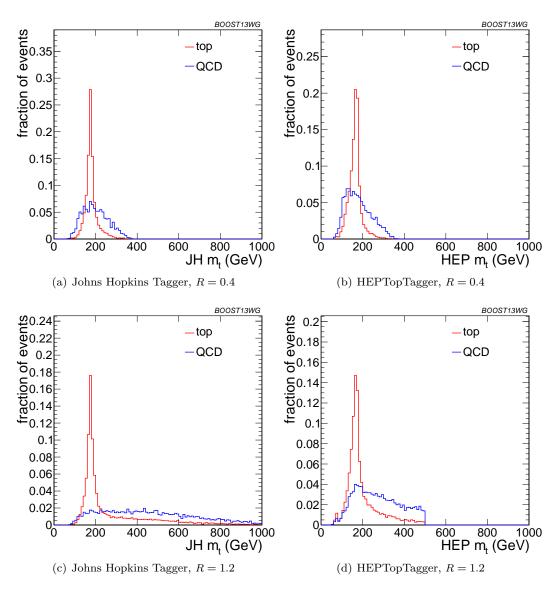

Fig. 26 Comparison of top mass reconstruction with the JH and HEPTopTaggers at different R using the anti- $k_{\rm T}$ algorithm, $p_{\rm T}=1.5-1.6$ TeV. Each histogram is shown for the working point optimized for best performance with m_t in the 0.3-0.35 signal efficiency bin, and is normalized to the fraction of events passing the tagger. In this and subsequent plots, the HEPTopTagger distribution cuts off at 500 GeV because the tagger fails to tag jets with a larger mass.

of the taggers. We do see a 20-50% improvement in performance when combining all outputs, which sug-993 gests that the different algorithms used to identify the pand W for different taggers contains complemen-995 tary information.

In Figure 38 we present the results for multivariable⁹⁹⁷ combinations of the top tagger outputs with and with-⁹⁹⁸ out shape variables. We see that, for both the HEP-⁹⁹⁹ TopTagger and the JH tagger, the shape observables⁹⁰⁰⁰ contain additional information uncorrelated with the⁹⁰¹ masses and helicity angle, and give on average a fac¹⁰⁰² tor 2-3 improvement in signal discrimination. We see⁹⁰⁰³ that, when combined with the tagger outputs, both⁹⁰⁴

the energy correlation functions $C_2 + C_3$ and the N-subjettiness ratios $\tau_{21} + \tau_{32}$ give comparable performance, while the Qjet mass volatility is slightly worse; this is unsurprising, as Qjets accesses shape information in a more indirect way from other shape observables. Combining all shape observables with a single top tagger provides even greater enhancement in discrimination power. We directly compare the performance of the JH and HEPTopTaggers in Figure 38(c). Combining the taggers with shape information nearly erases the difference between the tagging methods observed in Figure 37; this indicates that combining the shape information with the HEPTopTagger identifies the difference between

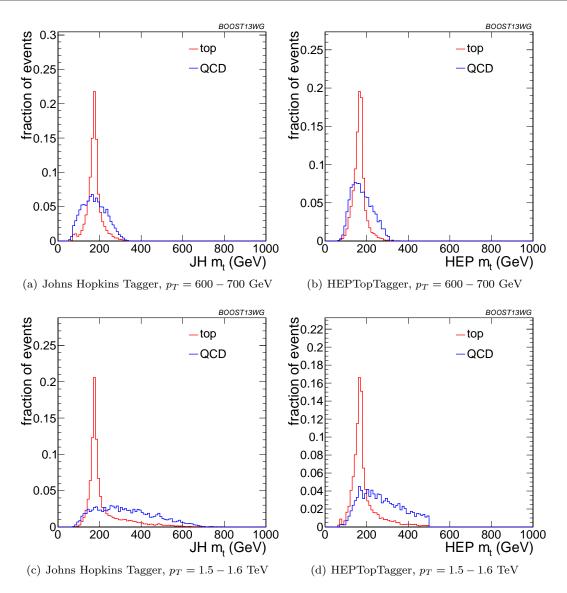

Fig. 27 Comparison of top mass reconstruction with the JH and HEPTopTaggers at different p_T using the anti- k_T algorithm, R = 0.8. Each histogram is shown for the working point optimized for best performance with m_t in the 0.3 - 0.35 signal efficiency bin, and is normalized to the fraction of events passing the tagger.

ences between signal and background missed by the tag_{*019} ger alone. This also suggests that further improvement₀₂₀ to discriminating power may be minimal, as various₀₂₁ multivariable combinations are converging to within a₀₂₂ factor of 20% or so.

In Figure 39 we present the results for multivari₁₀₂₄ able combinations of groomer outputs with and without shape variables. As with the tagging algorithms, com₁₀₂₅ binations of groomers with shape observables improves₀₂₆ their discriminating power; combinations with $\tau_{32} + \tau_{21027}$ perform comparably to those with $C_3 + C_2$, and both₀₂₈ of these are superior to combinations with the mass₀₂₉ volatility, Γ . Substantial improvement is further possi₁₀₃₀ ble by combining the groomers with all shape observ₁₀₃₁

ables. Not surprisingly, the taggers that lag behind in performance enjoy the largest gain in signal-background discrimination with the addition of shape observables. Once again, in Figure 39(c), we find that the differences between pruning and trimming are erased when combined with shape information.

Finally, in Figure 40, we compare the performance of each of the tagger/groomers when their outputs are combined with all of the shape observables considered. One can see that the discrepancies between the performance of the different taggers/groomers all but vanishes, suggesting perhaps that we are here utilising all available signal-background discrmination information,

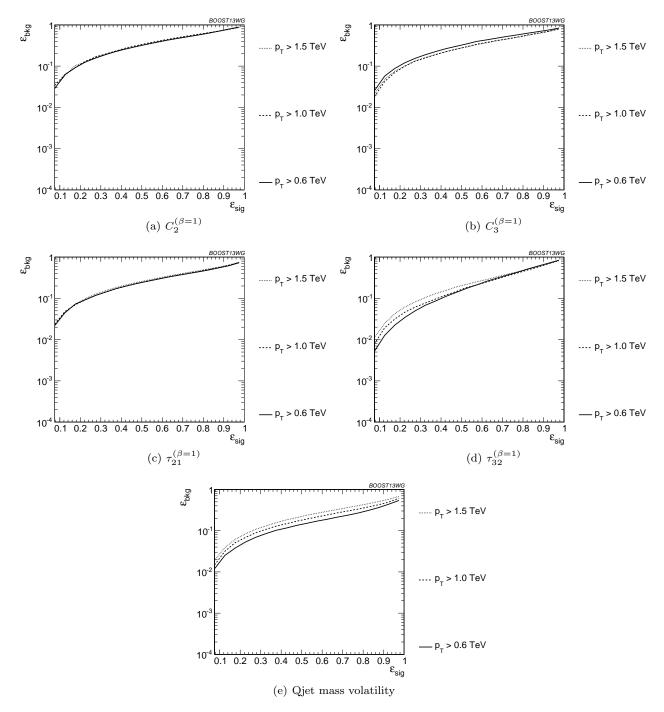

Fig. 28 Comparison of individual jet shape performance at different p_T using the anti- k_T R=0.8 algorithm.

and that this is the optimal top tagging performance that could be achieved in these conditions.

Up to this point we have just considered the com¹⁰⁴² bined multivariable performance in the p_T 1.0-1.1 TeV⁰⁴³ bin with jet radius R=0.8. We now compare the BDT⁰⁴⁴ combinations of tagger outputs, with and without shape⁰⁴⁵ variables, at different p_T . The taggers are optimized⁰⁴⁶ over all input parameters for each choice of p_T and sig¹⁰⁴⁷

nal efficiency. As with the single-variable study, we consider anti- k_T jets clustered with R=0.8 and compare the outcomes in the $p_T=500-600$ GeV, $p_T=1-1.1$ TeV, and $p_T=1.5-1.6$ TeV bins. The comparison of the taggers/groomers is shown in Figure 41. The behaviour with p_T is qualitatively similar to the behaviour of the m_t observable for each tagger/groomer shown in Figure 31; this suggests that the p_T behaviour of the

In Figure 42, we show the p_T dependence of BDTo75 combinations of the JH tagger output combined witho76 shape observables. We find that the curves look nearly077 identical: the p_T dependence is dominated by the top078 mass reconstruction, and combining the tagger outputs079 with different shape observables does not substantially080 change this behaviour. The same holds true for trim1081 ming and pruning. By contrast, HEPTopTagger ROC082 curves, shown in Figure 43, do change somewhat when083 combined with different shape observables; due to the084 suboptimal performance of the HEPTopTagger at high085 p_T , we find that combining the HEPTopTagger with086 $C_3^{(\beta=1)}$, which in Figure 28(b) is seen to have some modest improvement at high p_T , can improve its performance. Combining the HEPTopTagger with multiple shape observables gives the maximum improvement in

performance at high p_T relative to at low p_T .

In Figure 44 we compare the BDT combinations of tagger outputs, with and without shape variables, at different jet radius R in the $p_T = 1.5 - 1.6$ TeV bin. The taggers are optimized over all input parameters for each choice of R and signal efficiency. We find that, for all taggers and groomers, the performance is always best at small R; the choice of R is sufficiently large to admit the full top quark decay at such high p_T , but is small enough to suppress contamination from additional radiation. This is not altered when the taggers are combined with shape observable. For example, in Figure 45 is shown the depedence on R of the JH tagger when combined with shape observables, where one can see that the R-dependence is identical for all combinations. The same holds true for the HEPTopTagger, trimming, and pruning.

7.4 Performance at Sub-Optimal Working Points

To address this concern, we replicate our analyses, but only optimize the top taggers for a particular $p_T/R/\text{efficiency}$ and apply the same parameters to other scenarios. This allows us to determine the extent to which re-optimization is necessary to maintain the high signal-background discrimination power seen in the top tagging algorithms we study.

The shape observables typically do not have any input parameters to optimize. Therefore, we focus on the taggers and groomers, and their combination with shape observables, in this section.

Optimizing at a single p_T : We show in Fig. 46 the performance of the top taggers with all input parameters optimized to the $p_T = 1.5 - 1.6$ TeV relative to the performance optimized at each p_T . We see that while the performance degrades by about 50% when the high p_T optimized points are used at other momenta, this is only an O(1) adjustment of the tagger performance, with trimming and the Johns Hopkins tagger degrading the most. The jagged behaviour of the points is due to the finite resolution of the scan. We also observe a particular effect associated with using suboptimal taggers: since taggers sometimes fail to return a top candidate, parameters optimized for a particular efficiency ε_S at $p_T = 1.5 - 1.6$ TeV may not return enough signal candidates to reach the same efficiency at a different p_T . Consequently, no point appears for that p_T value. This is not often a practical concern, as the largest gains in signal discrimination and significance are for smaller values of ε_S , but it is something that must be considered when selecting benchmark tagger parameters and signal efficiencies.

The degradation in performance is more pronounced for the BDT combinations of the full tagger outputs (see Fig. 47), particularly at very low signal efficiency where the optimization picks out a cut on the tail of some distribution that depends precisely on the p_T/R of the jet. Once again, trimming and the Johns Hopkins tagger degrade more markedly.

Similar behaviour holds for the BDT combinations of taggers + shape observables, although we do not show the plots here because they look similar to Fig. 47.

Optimizing at a single R:

We perform a similar analysis, optimizing tagger parameters for each signal efficiency at R=1.2, and then use the same parameters for smaller R. We show the ratio of the performance of the top taggers with all input parameters optimized to the R=1.2 values compared to input parameters optimized separately at each radius, in Fig. 48. While the performance of each observable degrades at small $\epsilon_{\rm sig}$ compared to the optimized

Up until now, we have re-optimized our tagger and $_{14}$ groomer parameters for each p_T , R, and signal efficiency $_{142}$ working point. In reality, experiments will choose a fi₁₁₄₃ nite set of working points to use. How do our results $_{144}$ hold up when this is taken into account?

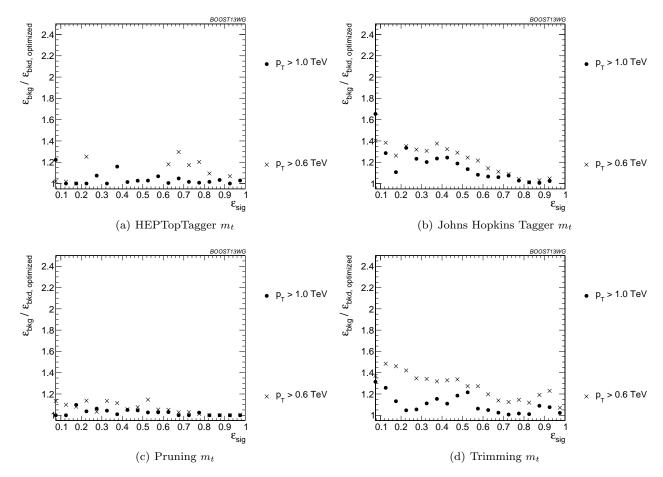

Fig. 46 Comparison of top mass performance of different taggers at different p_T using the anti- k_T R=0.8 algorithm; the tagger inputs are set to the optimum value for $p_T = 1.5 - 1.6$ TeV.

1181

search, the HEPTopTagger fares the worst as the ob₁₁₆₇ served is quite sensitive to the selected value of R. It₁₆₈ is not surprising that a tagger whose top mass recon₁₁₆₉ struction is susceptible to background-shaping at large₁₇₀ R and p_T would require a more careful optimization of parameters to obtain the best performance.

The same holds true for the BDT combinations of the full tagger outputs (see Fig. 49). The performance for the sub-optimal taggers is still within an O(1) fac $_{1174}$ tor of the optimized performance, and the HEPTop $_{1175}$ Tagger performs better with the combination of all of $_{176}$ its outputs relative to the performance with just $m_{t_{1177}}$ The same behaviour holds for the BDT combinations of tagger outputs and shape observables.

Optimizing at a single efficiency:

The strongest assumption we have made so far isise that the taggers can be reoptimized for each signal effiriss ciency point. This is useful for making a direct compartise ison of different top tagging algorithms, but is not particularly practical for the LHC analyses. We now continuous

sider the effects when the tagger inputs are optimized once, in the $\varepsilon_S = 0.3 - 0.35$ bin, and then used to determine the full ROC curve. We do this at $p_T = 1 - 1.1$ TeV and with R = 0.8.

The performance of each tagger, normalized to its performance optimized in each bin, is shown in Fig. 50 for cuts on the top mass and W mass, and in Fig. 51 for BDT combinations of tagger outputs and shape variables. In both plots, it is apparent that optimizing the taggers in the 0.3-0.35 efficiency bin gives comparable performance over efficiencies ranging from 0.2-0.5, although performance degrades at small and large signal efficiencies. Pruning appears to give especially robust signal/background discrimination without re-optimization, possibly due to the fact that there are no absolute distance or p_T scales that appear in the algorithm. Figs. 50-51 suggest that, while optimization at all signal efficiencies is a useful tool for comparing different algorithms, it is not crucial to achieve good top-tagging performance in experiments.

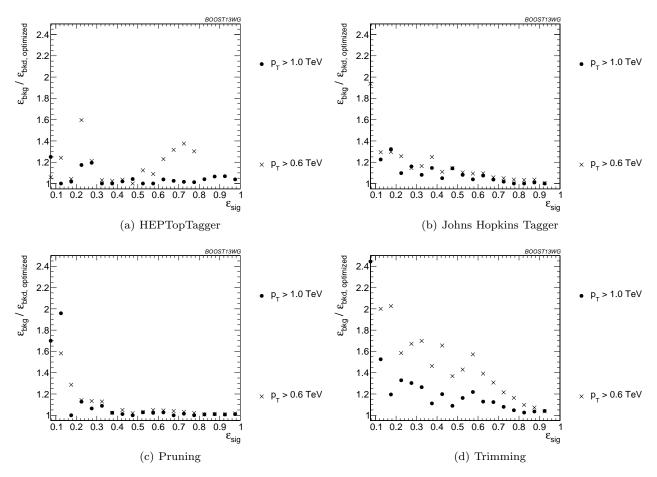

Fig. 47 Comparison of BDT combination of tagger performance at different p_T using the anti- k_T R=0.8 algorithm; the tagger inputs are set to the optimum value for $p_T = 1.5 - 1.6$ TeV.

7.5 Conclusions

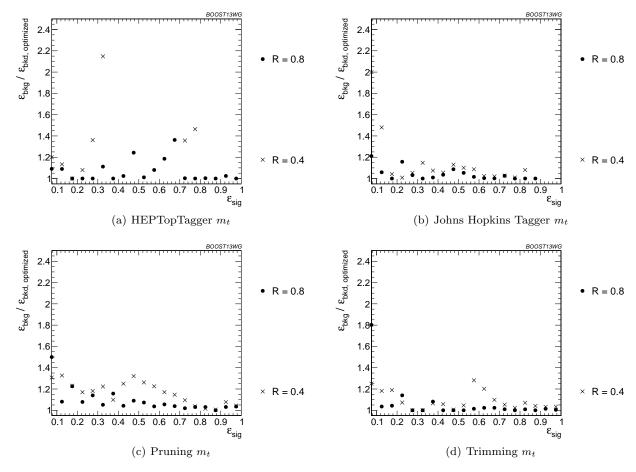

Fig. 48 Comparison of top mass performance of different taggers at different R in the $p_T = 1500 - 1600$ GeV bin; the tagger inputs are set to the optimum value for R = 1.2.

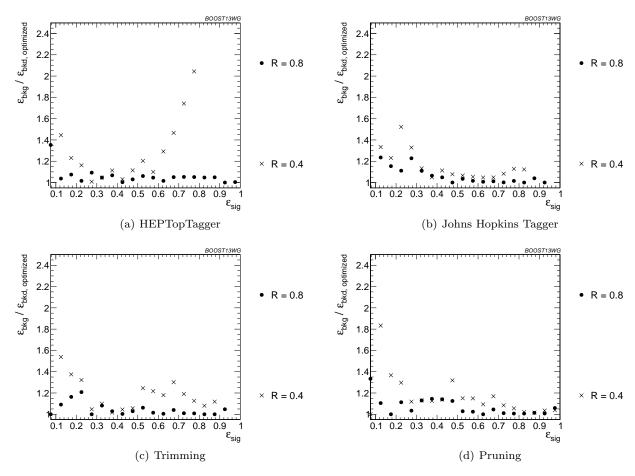

Fig. 49 Comparison of tagger and jet shape performance at different radius at $p_T = 1.5\text{-}1.6 \text{ TeV}$; the tagger inputs are set to the optimum value for R = 1.2.

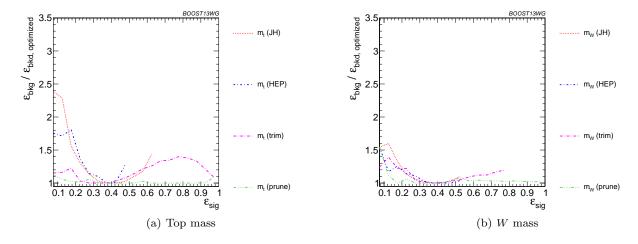

Fig. 50 Comparison of single-variable top-tagging performance in the $p_T = 1-1.1$ GeV bin using the anti- k_T , R=0.8 algorithm; the inputs for each tagger are optimized for the $\varepsilon_{\rm sig} = 0.3-0.35$ bin.

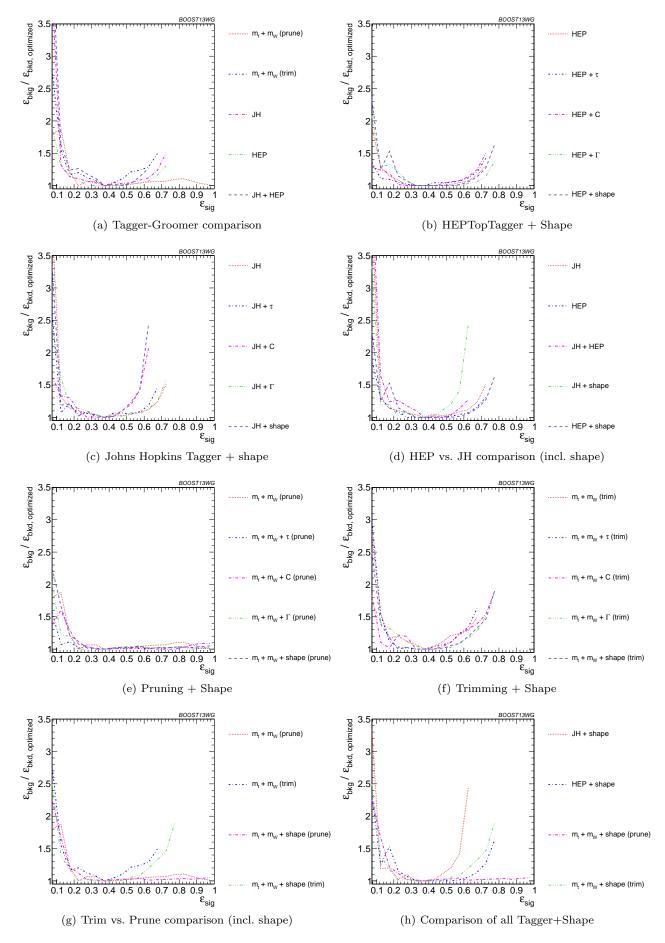

Fig. 51 The BDT combinations in the $p_T=1-1.1$ TeV bin using the anti- k_T R=0.8 algorithm. Taggers are combined with the following shape observables: $\tau_{21}^{(\beta=1)} + \tau_{32}^{(\beta=1)}$, $C_2^{(\beta=1)} + C_3^{(\beta=1)}$, $\Gamma_{\rm Qjet}$, and all of the above (denoted "shape"). The inputs for each tagger are optimized for the $\varepsilon_{\rm sig}=0.3-0.35$ bin.

8 Summary & Conclusions

This report discussed the correlations between observ_{T211} ables and looked forward to jet substructure at Run II²¹² of the LHC at 14 TeV center-of-mass collisions eneer¹²¹³ gies.
